Acknowledgements

The Guidelines Development Group (APPENDIX I) thank the following for their assistance and support in the development of this document:

- School of Health and Social Care, Teesside University;
- South Tees Hospitals NHS Foundation Trust;
- County Durham and Darlington NHS Foundation Trust;
- Middlesbrough and Redcar & Cleveland Community Services;
- North Tees and Hartlepool NHS Foundation Trust;
- York Hospitals and NHS Foundation Trust;
- Newcastle upon Tyne Hospitals NHS Foundation Trust;
- Delphi expert panel (APPENDIX F); and
- The Chartered Society of Physiotherapy.

We are also specifically grateful to Anne Jackson, Ralph Hammond and especially Emma Crumpton for their valued contributions.

These clinical guidelines were endorsed by the Good Practice Panel of the Chartered Society of Physiotherapy in December 2010. The endorsement process has included review by relevant external experts as well as peer review. The rigour of the appraisal process can assure users of the guidelines that the recommendations for practice are based on a systematic process of identifying the best available evidence at the time of endorsement.

Version 1.2 contains changes to the front cover and amended citation information.
Version 1.3 contains a corrected title to Table 3d and removal of redundant rows in Tables 3c and 3d (the authors thank Corinne Birch MCSP for bringing these items to their attention). The recommendation to use the terminology ‘pain-predominant’ and ‘stiffness-predominant’ is made explicit in Summary Table 1.6.

Major update of the standard physiotherapy section due: 2015.

Funding: This guideline development received no financial support.

Competing interests: None known.

Introduction

Please start here!

These guidelines are meant to be accessible to a broad spectrum of readers (see ii. Scope, below). So, as far as possible, we have written them in non-technical language; but in some places, technical language and concepts have been unavoidable. We have differentiated between non-technical and technical sections by using the following symbols:

- = Non-technical
- = Technical

Preamble

An estimated 50-80% of people with shoulder pain don’t seek medical attention for it. Despite this, shoulder pain is the third most common musculoskeletal reason for people to visit their GPs, and around 15% of these people are referred for physiotherapy in the three years following their initial consultations (reviewed by Linsell et al 2006). Others will consult a physiotherapist in the first instance. For physiotherapists, therefore, as well as sufferers and GPs among others, shoulder pain is a significant problem.

Contracted (frozen) shoulder is an important type of shoulder pain. More specifically, it is a combination of shoulder pain and stiffness that causes sleep disturbance and marked disability, and which runs a prolonged course. In some cases, it does not resolve completely (Bunker 2009). Its prevalence appears to vary by setting. For example, Walker-Bone et al (2004) conducted a large, UK-based primary care study, comprising a questionnaire survey and subsequent physical examination of respondents who reported shoulder pain, and found that contracted (frozen) shoulder affected 8.2% of men and 10.1% of women of working age. In contrast, based on his extensive tertiary care experience as a specialist shoulder surgeon, Bunker (2009) estimates that contracted (frozen) shoulder affects only 0.75% of the population. A plausible explanation for this discrepancy is that, by definition, only the most resistant cases are seen in the tertiary (and to a lesser extent, the secondary) care settings. Since physiotherapy spans all three care settings, individual physiotherapists might encounter contracted (frozen) shoulder often; this, added to the unpleasant nature of the condition, makes it important to identify the most effective ways for physiotherapists to diagnose it, evaluate it and manage it. But no detailed physiotherapy guidelines for contracted (frozen) shoulder have hitherto been published either in the UK or abroad.

---

1 Primary care refers to community-based healthcare. Secondary care is hospital-based, whereas tertiary care—also hospital-based—is specialised consultative care.
In the UK in particular, this leaves a vacuum of accessible information at a critical time. Widespread freezing of physiotherapist posts in the NHS has had profound implications for physiotherapy graduate employment, student recruitment and academic staff retention, and thus for patient care. Looking to the coming decade, the Chief Executive of the Chartered Society of Physiotherapy (CSP), summarising the implications of the Darzi report (Department of Health 2008), has observed that ‘CSP members will have to ... make both the business case and the clinical case for physiotherapy at a local level’ (Gray 2008). Meeting these unprecedented challenges requires physiotherapists to be effective, to evidence their effectiveness, and to make healthcare commissioners aware of this evidence. Unfortunately, despite dramatic increases in the quality and quantity of physiotherapy research over recent decades, implementation of the findings by clinical physiotherapists and commissioners has been scanty.

‘Priorities for physiotherapy research in the UK’ reports six consistent barriers to evidence-based practice (Chartered Society of Physiotherapy 2002). Four of these:

- shortage of time;
- the need to develop skills in critical appraisal and the understanding of statistics;
- difficulty translating findings into local clinical practice; and
- problems accessing the evidence

may potentially be addressed or circumvented by guidelines. Furthermore, by highlighting areas where future research is required, guidelines may indirectly address the fifth consistent barrier,

- a lack of high quality research.

Guidelines can also make a case for the provision of specific treatments, as well as influencing commissioning. Both factors may help physiotherapists better to meet their patients’ identified needs.

The development of these evidence-based clinical guidelines on the physiotherapy diagnosis, assessment and physiotherapy management of contracted (frozen) shoulder is therefore timely.

Scope

These guidelines are about ‘contracted (frozen) shoulder’ in people aged 18 and over. Based on the best available research evidence, they focus on physiotherapy but set it in context, giving an overview of the diagnosis and management possibilities for this condition, from initial consultation (e.g. by a GP) to, if necessary, operative care. The guidelines target professionals who are directly or indirectly involved in caring for people with contracted (frozen) shoulder—physiotherapy teachers and practitioners foremost, but also commissioners/providers of healthcare, GPs, orthopaedic surgeons, radiologists (doctors who specialise in X-rays and other types of medical imaging) and rheumatologists (doctors whose specialty includes the non-operative management of joint problems) and others. Not least, they were written in plain English, because we intended them to be accessible to patients and their representative organisations. To help us in achieving
this aim, we involved a Delphi expert panel, which included patients and patient representatives among others (see footnote^2).

**Exclusions**

We specifically do not intend the guidelines to apply to:

- pain from causes other than contracted (frozen) shoulder; or shoulder pain or stiffness secondary to:
  - stroke;
  - significant trauma (e.g. fracture or dislocation);
  - surgery (except in relation to operations undertaken to treat contracted (frozen) shoulder, such as manipulation under anaesthetic); or
  - systemic inflammatory conditions (e.g. rheumatoid arthritis).

**Aims and objectives**

Through the development of the guidelines we have aimed to improve patient care by:

- addressing the clinical question, ‘what is best practice in the diagnosis, assessment and physiotherapy management of contracted (frozen) shoulder?’; and
- facilitating best practice in physiotherapists’ diagnosis, assessment and physiotherapy management of contracted (frozen) shoulder.

These aims have taken account of pain, movement and patient-reported outcome measures (PROMs).

Our objectives have been to:

- identify and critically appraise the best available evidence relating to the diagnosis and assessment of contracted (frozen) shoulder;
- systematically review the best available evidence relating to the physiotherapy management of contracted (frozen) shoulder;
- make *general recommendations*, derived by transparent processes from the best available evidence, for the diagnosis and assessment of contracted (frozen) shoulder;
- make graded recommendations, again derived by transparent processes from the best available evidence, for the physiotherapy management of contracted (frozen) shoulder;
- highlight areas where further research is required;
- help implement evidence, as a basis both for optimising practice and influencing healthcare commissioning;
- enable people to take a more active role in their treatment if they wish to do so; and
- develop guidelines that are user-friendly and practical.

---

^2 We intended the guidelines as a resource for patients as well as healthcare professionals. However we were advised by our Delphi panellists to produce a separate patient information leaflet.
Protocol

As a measure against introducing bias into the guidelines, we developed a protocol in advance, and adhered to this throughout the development process. Any deviations from the protocol have been explicitly justified.

Key research concepts and methods in brief

This section introduces some key concepts and briefly explains how we developed the guidelines. For the full methods, see APPENDIX A.

Clinical trials

The guidelines are based on evidence from clinical trials. There are several types of clinical trials. All investigate a study ‘sample’: a group of patients meant to be representative of the population of people with the same condition. Randomised controlled trials (RCTs) are considered the best clinical trials because they are least prone to bias. In RCTs, each patient in the sample is randomly allocated to either a treatment group or a ‘control’ group, resulting in a fair distribution of condition severity and other key characteristics across the groups. The groups are tested on a chosen measure (called an ‘outcome measure’) at the start and at the end of the trial. If the randomisation was effective, one would expect the outcomes to be comparable at the start of the trial. Furthermore, if the treatment made a difference, one would expect the outcomes to be different at the end of the trial. Based on the results in their study sample, researchers use statistical tests to make inferences about how the population would respond to the same treatment. Valid inferences depend on the sample really being representative of the population, a property called ‘external validity’. Quasi -RCTs differ from RCTs in that people are not allotted to groups in a truly random fashion, but by some other means e.g. according to whether their birth date is odd or even. Quasi-RCTs are considered inferior to RCTs because they are more prone to bias, but better than non-randomised controlled trials, in which patients are allocated to groups without any randomisation.

Systematic reviews and meta-analyses

Individual controlled trials may not include enough patients to detect moderate to small differences between the treatment and control groups, even though the differences may be clinically important. A solution to this would be to have much larger trials, but these are often prevented by practical constraints. An alternative is to find, collate and evaluate all the trials that have investigated the condition of interest, ideally using a transparent, systematic process (a ‘systematic review’); then, if a number of the trials are sufficiently similar, to perform a special statistical test called a meta-analysis. Meta-analyses combine the results of two or more similar studies and increase our ability to detect differences between groups. Systematic reviews that include a meta-analysis (if this is appropriate) are now regarded as the highest level of research evidence where trials are concerned; but, in fact, not all such reviews are good. Inappropriate meta-analyses, for example, may give meaningless or misleading results.
Cochrane Collaboration and Cochrane reviews
The Cochrane Collaboration ([http://cochrane.co.uk/en/collaboration.html](http://cochrane.co.uk/en/collaboration.html)) is an international, not-for-profit and independent organisation dedicated to producing systematic reviews (including meta-analyses, as appropriate) of high methodological quality: Cochrane reviews are generally regarded as the ‘gold standard’ of systematic reviews.

Search for Cochrane reviews
We searched in the on-line Cochrane Library ([http://www.cochrane.org/](http://www.cochrane.org/)) for Cochrane reviews on treatments that physiotherapists might use for shoulder pain. We found four, respectively covering ‘standard physiotherapy’ (Green, Buchbinder & Hetrick 2003), acupuncture (Green, Buchbinder & Hetrick 2005), corticosteroid injections (Buchbinder, Green & Youd 2003) and distension therapy, which involves injecting a large volume of fluid to stretch out the joint (Buchbinder et al 2008). For this version of the guidelines (version 1.3) our focus was ‘standard physiotherapy’ treatments, corresponding to those modalities which a newly graduated physiotherapist in the UK would have at his or her disposal, although this has involved comparison with other interventions. The relevant Cochrane review (Green, Buchbinder & Hetrick 2003) had considered for inclusion RCTs and quasi-RCTs up to June 2002.

Systematic review
We noted the trials included in the above Cochrane reviews, obtained the trials’ original reports and filtered out those that were not applicable to the present guidelines. We then derived our search strategy from the Cochrane reviews, increasing its specificity to contracted (frozen) shoulder and limiting it to reports in the English language, and ran searches on the Ovid MEDLINE, AMED, CINAHL and EMBASE databases from 2001 to 09 July 2008, using the OvidSP platform. Thus our search period overlapped with that of the earliest of the four Cochrane reviews (Green, Buchbinder & Hetrick 2003), whose cut-off for inclusion of trials was June 2002. Using methodology based on that in the Cochrane Handbook (2009) we then evaluated the trials and, with special focus on results’ clinical importance, conducted analyses or, if appropriate, meta-analyses.

Questionnaire survey of CSP members
We conducted a survey of Chartered Society of Physiotherapy (CSP) members in order to:

- obtain a snapshot of physiotherapists’ approaches to diagnosing and treating contracted (frozen) shoulder at the present time, enabling us to:
  - identify the treatments currently in use and focus on these in our overview of interventions (section 1.6);
  - set the overview of interventions in context;
  - establish a baseline against which the guidelines’ impact might be evaluated; and
- identify discrepancies between practice and research.

We posted notices on eight special interest networks of the interactive CSP (iCSP) website, to whose subscribers contracted (frozen) shoulder might be of interest. The notices invited subscribers to follow a link to self-administered, on-line questionnaire. The questionnaire required
respondents to state whether or not they had a ‘special interest’ in contracted (frozen) shoulder, because we were interested to see whether this distinction affected the diagnostic and management strategies they used; and to differentiate according to whether pain or stiffness was the primary problem. A full version of the survey report is available in full elsewhere (Hanchard et al 2010).

**GRADE system**

Finally, we graded the quality of the evidence and derived our recommendations using the GRADE system, which is recommended by the Cochrane Collaboration, transparent, and increasingly in standard use. Specifically, we graded the quality of the evidence using GRADEprofiler version 3.2.2 software, which was developed by the GRADE Working Group. Aspects of quality include:

- Design and limitations (risk of bias);
- inconsistency (which occurs when trials’ results do not agree);
- indirectness (which occurs when the trials’ results are inapplicable to the population of interest);
- imprecision (which occurs when the estimates of effect are wide); and
- publication bias (underestimation or overestimation of effects due to selective publication of trials).

The resulting tables—GRADE evidence profile tables—are in APPENDIX E.

Our recommendations for management have taken the quality of the evidence into account. When evidence is graded ‘high’, it means that further research is unlikely to change our confidence in the estimated effect; when it is ‘moderate’, further research is likely to influence our confidence in the estimated effect, and may change the estimate; when it is ‘low’, further research is very likely to seriously influence our confidence in the estimated effect, and is likely to change the estimate; and when it is ‘very low’, any estimate of effect is very uncertain. With the quality of the evidence taken into account, potential benefits were weighed against potential harms and, if feasible, a recommendation for management made. As recommended by the GRADE Working Group, we used four classifications of recommendation: ‘do it’, ‘probably do it’, ‘probably don’t do it’ and ‘don’t do it’. ‘Do it’ or ‘don’t do it’ indicate a judgement that most well informed people (i.e. patients) would make. ‘Probably do it’ or ‘probably don’t do it’ indicate a judgement that a majority of well informed people would make but a substantial minority would not’ (GRADE Working Group 2004).

‘A recommendation to use or withhold an intervention does not mean that all patients should be treated identically. Nor does it mean that clinicians should not involve patients in the decision, or explain the merits of the alternatives. However, because most well informed patients will make the same choice, the explanation of the merits of the alternatives may be relatively brief. A recommendation is intended to facilitate an appropriate decision for an individual patient or a population. It should therefore reflect what people would likely choose, based on the evidence and their own values or preferences in relation to the expected outcomes. A recommendation to “probably do something” indicates a need for
clinicians to more fully and carefully consider patients’ values and preferences when offering them the intervention.’ (GRADE Working Group 2004)

In instances where the evidence was insufficient to make a recommendation for practice, we reserved judgement.

We have not considered economic data in this iteration of the guidelines.

Feedback from target audience
We engaged representative members of our diverse target audience (a Delphi expert panel) to feedback to us during the development process, thus ensuring the guidelines’ ‘fitness for purpose’ (APPENDIX G).

Future versions
Future versions of these guidelines will incorporate acupuncture, corticosteroid injections and capsular distension, thus encompassing other interventions that might be used by physiotherapists. The guidelines’ electronic format will facilitate this staged process.

Structure

The guidelines are presented in three parts, as follows.

Part 1: Background, diagnosis, assessment and overview of strategies for managing contracted (frozen) shoulder

Part 2: Systematic review and meta-analysis of treatment interventions

This is a systematic review of treatment interventions which, in this first version (now version 1.3), is restricted to ‘standard physiotherapy’. We have defined ‘standard physiotherapy’ as any intervention(s) that might be undertaken by a graduate physiotherapist without additional training, namely: advice; exercise therapy; manual therapy; electrotherapy; heat or cold treatments; ultrasound; or any combination of these.

Part 3: Recommendations for management of contracted (frozen) shoulder

Recommendations for management are derived from the systematic review using the GRADE system.

Part 4: Recommendations for research

Part 5: APPENDICES
References to Introduction

1. Background, diagnosis, assessment and overview of strategies for managing contracted (frozen) shoulder

1.1. Anatomy of the shoulder

The shoulder joint is a ball and socket joint between between the head of humerus (the upper arm bone) and the scapula (shoulder blade). A membrane (synovial membrane) lining the non-articulating surfaces constantly secretes and reabsorb a slippery lubricant, synovial fluid; the articulating surfaces are covered with smooth cartilage; and the whole is enclosed in a flexible fibrous capsule, which is attached to bone at the margins of the articulating surfaces, but not to the articulating surfaces themselves. In some other joints, the capsule has an important stabilising function—for example at the knee, where, at the sides, the capsule is condensed into the tough collateral ligaments that prevent side-to-side movement. But this is less so at the shoulder, where the capsule must be relatively lax to allow for mobility in all directions. This laxity, which gives the joint a surprisingly large capacity—a normal shoulder joint holds 10-30 ml of fluid (Lee et al 2002)—is greatest underneath the joint in the axilla (armpit), where it forms the redundant axillary fold. The other aspects of the joint capsule blend with the tendons of the rotator cuff, the shoulder’s deep stabilising and controlling muscles. Specifically, the tendons of teres minor and infraspinatus lie behind (posteriorly) and merge with the rear of the capsule; the tendon of supraspinatus lies above (superiorly) and merges with the top of the capsule; and the tendon of subscapularis lies in front (anteriorly) and merges with the front of the capsule. There is no clear demarcation between the tendons, which merge with each other as well as the capsule, except anteriorly, between supraspinatus and subscapularis, where there is a deficiency in the rotator cuff called the rotator interval. At the shoulder joint, stability is a dynamic affair, brought about by interplay between the rotator cuff’s components and other muscles.

The rotator cuff is separated from the bone, ligament and muscle overlying it by a bursa, a sac lined with synovial membrane, which, like synovial membrane inside the joint, secretes slippery synovial fluid. This bursa which, at about the size of the palm of the hand, is the largest in the body, prevents friction between the rotator cuff and its adjacent structures. In some circumstances (discussed by Hanchard, Cummins & Jeffries 2004), the bursa is unable to fulfil this role, and allows painful pinching of the soft tissues between bony protuberances on the humerus (the humeral tuberosities) and the arch of bone and ligament above them (the acromion process and the coraco-acromial ligament) which extends from the scapula. This is subacromial or outlet impingement, which can lead to erosion of the rotator cuff. Other types of impingements can occur inside the shoulder joint, especially in sportspeople who forcibly move their shoulders to the extremes of range, menacing the deep surface of the rotator cuff tendons among other structures (Edelson & Teitz 2000, Gold et al 2003, Halbrecht, Tirman & Atkin 1999, Jobe 1996, 1997, Pappas et al 2006, Valadie et al 2000). The various impingements are the main intrinsic causes of shoulder pain, and therefore important differential diagnoses from contracted (frozen) shoulder. Neck problems are a common extrinsic cause of shoulder pain, which is why neck movements should be screened as part of a shoulder assessment.
Movements at the shoulder joint are defined in standard anatomical terms (FIGURES 1.1a-h). All of the movements, especially elevation, are augmented by movements of the scapula relative to the chest wall.
1.2. From ‘50s shoulder’ to ‘contracted (frozen) shoulder’: 📚
a tour of terminology and pathology

The terminology surrounding contracted (frozen) shoulder has been reviewed extensively by
Nobuhara (2003). In Japan, the condition has long been known as 50s shoulder. Nobuhara reports a
reference to this term in an eighteenth-century source, *Rigenshuran*, which offers, as an alternative
descriptor, ‘long-life disease’. It seems that to survive beyond 50 was noteworthy, then. Perhaps a painful shoulder was a small price to pay. According to Nobuhara (2003), *Rigenshuran* defines 50s shoulder as ‘pain in the arm and joints which develops at about age 50 at times, but improves after a while without the administration of drugs’. This catches some of the essence of contracted (frozen) shoulder, although it omits to mention stiffness, which is a key feature. Recognition of the condition took rather longer in the West. It was not until 1867 that the French surgeon E.S. Duplay reported the results of his surgical explorations, initially of post-traumatic stiff shoulders, and dignified these with the name ‘periarthritis scapulohumerale’. Later, he realised that this condition also occurred in the absence of trauma. He achieved the double distinction of having the condition named both by him (‘periarthritis scapulohumerale’) and for him (maladie de Duplay).

Mistakenly, Duplay and most of his contemporaries believed that the condition was primarily due to pathology in the subacromial-subdeltoid bursa (Lee et al 1973, Nobuhara 2003). Considering this, periarthritis (*peri* = around; *arthr* = joint; *itis* = inflammation) seems rather a vague term, since it could legitimately refer to inflammation of any tissue around a joint; but it may be this very vagueness that has accounted for its lasting appeal. In fact, ‘periarthritis’, and its variant ‘periartricular shoulder pain’, have remained in use to the present day (Lee et al 1973, Shehab & Adnam 2000, Nobuhara 2003). No more precise anatomically, and less so pathologically, is ‘frozen shoulder’, a label originated by the American surgeon E.A. Codman in his seminal book (1934). But this term has also stuck: so much so that we felt obliged to keep it in the title of these guidelines, albeit in brackets. Codman admitted that he was perplexed by the pathology of frozen shoulder. At first he, like Duplay, believed that the bursa played the primary role. Later, he implicated the tendons. This too was a false scent. However, his clinical description of patients with contracted (frozen) shoulder has hardly been bettered.

It comes on ‘slowly; [with] pain usually felt near the insertion of the deltoid’; inability to sleep on the affected side; painful and incomplete elevation and external rotation; restriction of both spasmodic and mildly adherent type; atrophy of the spinati; little local tenderness; [and] X-rays negative except for bone atrophy’ (Codman 1934).

Attention turned to the shoulder joint capsule as the source of problems with a series of surgical explorations in 10 patients by J.S. Neviaser, which he reported in 1945. Neviaser found that the capsules were thicker than normal and contracted: they gaped apart when he incised them with his scalpel. Additionally, he reported that in each case the capsule was abnormally adherent to the humerus, in the same way that sticky plasters are adherent to skin, but could be peeled off by repetitive rotational movements of the joint. In nine of the cases, he said, the capsule was also adherent to itself in the redundant axillary fold. Neviaser asserted that the primary pathology was not a periarthritis, and proposed the term “adhesive capsulitis” ... as descriptive of the pathology of “frozen shoulder”’ (Neviaser 1945). The term is widely used, especially in the USA. Meanwhile, the orthopaedic physician J.H. Cyriax had incriminated the joint capsule by deduction, and considered that Neviaser’s findings bore out his views (Cyriax 1982). The significance—indeed the

---

3 The deltoid is the muscle that gives the shoulder its rounded contour. Its ‘insertion’ is where it attaches to the humerus, about half way down the bone.

4 i.e. wasting of the supraspinatus and infraspinatus muscles.
existence—of adhesions has since been challenged (Bunker 1997, Bunker 2009, Omari & Bunker 2001), but Neviaser and Cyriax were right to incriminate the joint capsule.

Since Neviaser’s study, the advent of arthroscopic (keyhole) techniques has made surgical exploration of shoulder joints commonplace. As reviewed by Bunker (2009), one of the most striking features on arthroscoping a contracted (frozen) shoulder is capsular contracture: the capsule becomes tough and thickened, and its volume may shrink to as little as 3-4 ml. (This loss of capacity is also obvious when attempting to inject moderate volumes of fluid into affected shoulders.) Another striking feature is the formation of new blood vessels in the synovial membrane, especially in the rotator interval area, but also in the superior capsule, the posterior capsule and the redundant axillary fold. In cases where the pain is giving way to stiffness, these new blood vessels become embedded in thick scar, densest in the underlying capsule (Bunker 2009, Omari and Bunker 2001).

But the underlying pathology has been elusive. Some have argued that the fundamental process is inflammation; others that it is scarring; yet others that it is scarring produced in reaction to inflammation (Hand et al 2007). The last of these is logically appealing for a number of reasons: because frozen shoulder causes both pain and stiffness, but the stiffness outlasts the pain; because of the changes seen in relation to blood circulation; and also because painful contracted (frozen) shoulder may respond to injections of corticosteroid (Buchbinder, Green & Youd 2003), a potent suppressor of inflammation. Hand et al (2007) microscopically examined tissues from the rotator interval of 22 patients with frozen shoulder. This examination, combined with novel staining techniques, revealed large numbers of fibroblasts (cells that, among other things, produce scar); cells associated with chronic inflammation (Hand et al 2007); and an increase in blood vessels. On this basis, Hand et al (2007) have proposed that frozen shoulder does indeed represent a process in which inflammation leads to scarring. They have tentatively implicated mast cells in this link. Mast cells, which are among the inflammation-related cells they found, are known to control the proliferation of fibroblasts. Myofibroblasts, another cell type—a cross between fibroblasts and muscle cells, which cause scar to contract—may also be implicated in the pathology of frozen shoulder. Bunker (1997) and Omari and Bunker (2001) resorted to open surgery in patients with frozen shoulder that had responded to neither conservative measures nor manipulation under anaesthesia, and found abundant myofibroblasts in tissue taken from the rotator interval. Clearly, on a large scale, myofibroblasts could contribute to capsular contracture; and that Hand et al (2007) did not find significant numbers of these cells may reflect the fact that their patient population was less chronic. Another finding in capsular tissue from patients with frozen shoulder is the absence of certain enzymes that would normally be involved in the remodelling of scar tissue (Bunker 2009).

Regardless of the mechanism by which it comes about, contracture is such a striking feature of frozen shoulder that Bunker (2009) has suggested a further redesignation, ‘contracted (frozen) shoulder’, which we have adopted.

The subtypes of contracted (frozen) shoulder have also been inconsistently classified. Codman (1934)—and indeed Duplay—noted that the condition could be insidious or secondary to trauma.
Cyriax called the former monarticular infective [sic] arthritis (Cyriax & Troisier 1953, Cyriax 1954) then monarticular rheumatoid arthritis (Cyriax 1957), subsequently changing this, in deference to objections from the rheumatology community, to ‘steroid-sensitive arthritis’. (He found it responsive to injections of the corticosteroid hydrocortisone.) He called the latter traumatic arthritis (Cyriax & Troisier 1953, Cyriax 1954, 1957), though he later reported that these cases, too, were responsive to injection of corticosteroid: not hydrocortisone, but triamcinilone, which became available to him in 1970 (Cyriax 1982). Lundberg’s 1969 classification was into primary (of unknown cause) and secondary (to trauma). Others have since expanded Lundberg’s secondary category to include any association with another event or condition (reviewed by Kelley, McClure & Leggin 2009). In this connection, ‘another event’ would include trauma or cardiac- or neurosurgery; while ‘another condition’ would include diabetes, Dupuytren’s disease, Parkinson’s disease, osteoporosis, cardiorespiratory disease, stroke, high cholesterol or adrenocorticotrophic hormone (ACTH) deficiency (reviewed by Hand et al 2008, Kelley, McClure & Leggin 2009). This expanded classification is helpful, and will be adhered to here, but it is not universally recognised. For example, some writers, following Lundberg’s original classification system, would categorise contracted (frozen) shoulder in a person with diabetes as primary, providing it was non-traumatic in origin.

1.3. Diagnosing contracted (frozen) shoulder

This section describes the options for clinically diagnosing contracted (frozen) shoulder (establishing that the condition is present), looks at some of the strategies in use, based on the questionnaire survey of CSP members (Hanchard et al 2010) and makes suggestions.

Trials of treatments for shoulder pain vary in their inclusivity. Some evaluate treatments for mixed-type shoulder pain. Others represent an attempt to target specific types of shoulder pain. Green, Hetrick and Buchbinder (2003) note that trials of the second type are appealing to clinicians because they reflect the way in which clinicians work: clinicians treat different types of shoulder pain in different ways. As might be expected, contracted (frozen) shoulder and its subtypes go by many names in such trials. Also, the precise diagnostic criteria vary—often reflecting imprecise reporting—but, typically, they remain compatible with the clinical features described by Codman (1934).

There is a gradual onset of arm pain; the patient is unable to lie on the affected side; there is restriction of movements notably including elevation and external rotation; and all this in the face of negative X-rays. The condition runs a distinct course, divided into different phases by different authorities though, based on our survey (Hanchard et al 2010), we recommend a simple ‘pain-predominant’ or ‘stiffness-predominant’ classification. Essentially there is a phase of increasing pain and increasing stiffness, during which pain is the predominant complaint: at its height, pain is

---

5 Among people with diabetes or pronounced Dupuytren’s disease, contracted (frozen) shoulder is not only prevalent, but also potentially slower to resolve and more resistant to treatment (Bunker 2009).
present even at rest, extends down the arm past the elbow, disturbs sleep and prevents lying on the affected side (Cyriax 1982). Sleep disturbance, often the patient’s main reason for seeking help, is not especially helpful diagnostically, because the same symptom occurs with rotator cuff tears (reviewed by Hanchard, Cummins & Jeffries 2004). The pain abates leaving stiffness as the predominant complaint; then the condition ends—more or less—in resolution. Codman (1934) wrote that resolution was the rule within about two years, an assertion echoed by other authorities (e.g. Cyriax 1982); but a recent study of 223 patients referred to tertiary care with contracted (frozen) shoulder revealed that 38% had persistent mild symptoms at a mean follow-up time of 4.4 years from onset of symptoms (range 2-20 years), mostly pain; and that 3% had persistent severe symptoms with pain and loss of function. Those with the worst symptoms at the outset had the worst prognosis (Hand et al 2008).

Cyriax (1982) established that restriction of passive movement was necessary to make the diagnosis of contracted (frozen) shoulder, and this is now a generally accepted principle. He also introduced the concept of the capsular pattern, a pattern of limitation of passive movements which is unique to each joint and which, theoretically, always denotes ‘capsulitis’ (literally capsule inflammation). Cyriax defined the capsular pattern of the shoulder as the ratio between three passive movements, whereby external rotation is most restricted, abduction less, and internal rotation less still, with the rotations being tested in the elbow-at-side position (Cyriax 1982). In theory, a capsular pattern would be expected in contracted (frozen) shoulder, since some degree of capsulitis is likely to be present. Rundquist et al (2003) tested this hypothesis in 10 patients with stiffness predominant primary contracted (frozen) shoulder, using electromagnetic sensors to track the 3-dimensional positions of the trunk, scapula and humerus during external rotation, abduction and internal rotation—although these movements were active, not passive—and found a classical capsular pattern in seven. External rotation was the most restricted movement in eight, and the most or second most restricted in nine. In a subsequent study of 23 patients, Rundquist and Ludewig (2004) found that external rotation was most restricted, jointly most restricted, or second most restricted in 92%. Setting the details of the capsular pattern aside, this involvement of external rotation is not surprising. Contracted (frozen) shoulder is known to centre on the rotator interval (Bunker 1997, 2009), and in experiments on eight cadaveric shoulders, Harryman et al (1992) found that shortening the rotator interval capsule by approximately 1 cm reduced external rotation by a mean value of 37.7º (± standard deviation 20.8º). In contrast, abduction and internal rotation were hardly affected. At 60º of flexion, the reduction in external rotation dwindled to a relatively modest 17.8º (± 6.3º): a persuasive argument, too, for testing external rotation in the elbow-at-side position. In our survey of UK physiotherapists, we found the capsular pattern concept popular, but often misinterpreted. Many other respondents—more among those with a special interest—placed more emphasis on restriction of passive external rotation than its place in a multi-component pattern in diagnosing contracted (frozen) shoulder. This approach, which is simple, memorable, and unlikely to lead to confusion, is supported by Bunker (1997, 2009) and ourselves.

---

Passive movements are those which are performed for the patient, while his or her muscles are relaxed. These are distinct from active movements, which the patient produces of his or her own volition.
Differential diagnosis between contracted (frozen) shoulder and the impingement-type disorders causes some confusion. Specifically, it is to be expected that many standard tests for impingement will be positive in the pain-predominant phase of contracted (frozen) shoulder, because they involve stretching the joint capsule. This applies to Neer’s sign (Neer & Welsh 1977, Neer 1983), among others. Neer recognised this problem, and it was for this reason that he described Neer’s test, which involves injecting local anaesthetic under the acromial arch. Neer argued that in subacromial impingement, this would render his sign negative (Neer & Welsh 1977, Neer 1983). A simpler approach is to regard signs of contracted (frozen) shoulder as taking primacy over signs of impingement.

Finally, Codman’s (1934) observation, since amplified by Bunker (1997, 2009), that a normal X-ray is prerequisite to a definitive diagnosis of contracted (frozen) shoulder, warrants restating. Restricted passive external rotation and the capsular pattern are not unique to contracted (frozen) shoulder: locked dislocations restrict passive external rotation, and arthritis and joint fractures cause a capsular pattern. All are visible on X-ray, though orthogonal views\(^7\) (views taken at right angles) are recommended in order that abnormalities are not overlooked. It is perhaps unrealistic to expect that all patients presenting with the clinical features of contracted (frozen) shoulder will routinely be referred for X-ray, but it should be remembered that in the absence of this procedure the diagnosis is tentative. Care should therefore be taken during the history to rule out substantial trauma, systemic (body-wide) disease and general ill-health; specific examination should be made for crepitus (gross creaking or grating) on passive movement; and a poor response to treatment should promptly trigger further investigation.

### 1.4. Reproducibility of physical tests for contracted (frozen) shoulder, and general guidance on applying the physical tests

Is the capsular pattern a reproducible finding? One aspect of reproducibility concerns whether different testers agree on whether a capsular pattern is present. Nominal agreement of this type is necessary for the diagnosis to be reproducible. Hanchard, Howe and Gilbert (2004), conducted a standardised history and physical examination of 53 patients with mixed-stage shoulder pain. Patients were typically examined in standing, and universal goniometers (protractors for measuring joint angles) were made available to testers, although their use was optional. Agreements between testers (one expert and three non-expert) on diagnoses of contracted (frozen) shoulder were found to be respectively ‘good’, ‘very good’ and ‘very good’ (for those with a statistical turn of mind, \(\kappa = 0.63, 0.81\) and 0.82).

Another aspect of reproducibility goes beyond agreement on whether passive movements are ‘positive’ or ‘negative’ and concerns the extent to which there is agreement on the amount of available movement, measured in degrees. Quantitative agreement of this type is necessary for estimations of the condition’s severity to be reproducible. There are within-tester and between-testers elements. Specifically, the extent to which a single tester obtains similar values (in degrees)

---

\(^7\) A-P and axillary lateral views are normally taken
on successive measurements or estimates is termed within-tester agreement. The extent to which different testers obtain similar values is termed between-testers agreement. If its quantitative within-tester agreement is good (and it is otherwise valid), a test is useful for assessing a condition’s severity (and its progress and outcome), providing the same person takes the measurements. If its between-tester reliability is good (and it is otherwise valid), a test is useful for such assessment even if different people take the measurements.

With respect to within-tester agreement, Tveita et al (2008) took measurements a week apart in 32 patients with contracted (frozen) shoulder of three months’ to two years’ duration, using a digital, gravity-dependent measuring device (digital inclinometer). For measurements of rotation, their patients lay supine with 45° of shoulder abduction. Based on their results, they estimated that, 95 times out of 100, a change in passive external rotation of \( \geq 13^\circ \) would reflect real change; but that any smaller change would be indistinguishable from measurement error.

Regarding between-testers agreement, de Winter et al (2004) conducted a study in which two physiotherapists, again using a digital inclinometer, independently measured passive lateral rotation in 155 patients with mixed-stage shoulder pain. Rotation was measured with patients lying supine, and their elbows at their sides. In this sample, \( \geq 23^\circ \) change in passive external rotation was necessary to reflect real change 95 times out of 100. Terwee et al (2005) evaluated the agreement between two independent physiotherapist’s visual estimates of joint angles in a sample of 201 patients with mixed-stage shoulder pain. Patients were seated for the test movements, passive external rotation being tested with the elbow at the side. Visual estimation is standard practice for many—probably most—clinicians, who work within tight time constraints, and testing is very often done in an upright (sitting or standing) position, making the study particularly apposite. In their sample, changes in passive external rotation had to equal or exceed 35° in order to reflect true change 95 times out of 100, and Terwee et al observed that agreement was particularly low for patients in severe pain and with major disability. Furthermore, Croft et al (1994), who evaluated agreement on visual estimated ranges of shoulder movement between primary care physicians, concluded ‘external rotation is poorly reproducible because of systematic variation in examination technique and random variation in visual assessment’.

In individual clinical instances, agreement may be better or worse that demonstrated in the foregoing studies’ samples. The key messages here are that passive external rotation is fundamental to the diagnosis of contracted (frozen) shoulder, but an inexact tool for assessing the condition’s severity, progress and outcome; and that, in so far as it is used in these capacities, repeated measurements are more meaningful when taken by one tester than by several. Also, it would be expected that standardised technique would probably enhance both within-tester and between-testers reproducibility. Prerequisite to standardised technique are clear operational definitions, such as whether the end point of movement is considered to be the maximum attainable range or (more likely), the point at which pain occurs, increases or becomes intolerable; and these definitions should be made explicit on patients’ records. Stabilisation of the scapula or trunk is another important consideration and, especially if the test is performed in standing, great care should be taken to prevent trunk rotation. We suggest that external rotation be tested with the patient’s elbow at his or her side for optimal sensitivity to contracted (frozen) shoulder (Harryman et al 1992, Rundquist et al 2003, Rundquist & Ludewig 2004). In this position (FIGURE
1.2a), the tester can limit trunk rotation and, with his or her shoulder behind to the patient’s scapula, is well placed to detect scapular retraction. Even so, the tester should be realistic about the likely reproducibility of his or her estimations, perhaps thinking in terms of 30° increments rather than discrete degrees (FIGURE 1.2b). Where an estimate falls between two increments, the smaller could be taken.

![FIGURE 1.2a. A method for estimating passive external rotation (the key physical diagnostic test) in standing. The tester’s trunk hand stabilises the patient’s trunk; his trunk blocks scapular retraction and stabilises the patient’s elbow.](image)

![FIGURE 1.2b. Estimation of external rotation in 30° increments. Where an estimate falls between two values, the smaller can be taken.](image)

1.5. Other ‘tools’ for assessment

It is essential to reliably measure and document the effectiveness of our interventions, and to do this in a way that is meaningful for our patients. Both generic and specific outcome measures exist. A key advantage of generic measures is that they allow for comparison of people with different conditions, or for comparison against normative values. Their main disadvantages are that, compared to specific outcome measures, they may be insensitive; that they may be prone to ‘floor’ or ‘ceiling’ effects; and that they may lack face validity. Region/condition-specific outcome measures are of restricted use for comparisons, but on the other hand, they tend to be sensitive and to have face validity (Finch et al 2002).

Some region/condition specific outcome measures are for completion by the patient, and the additional advantage of these is that they cost the clinician no time. There are numerous validated
outcome measures of this type. An indicative (by no means comprehensive) selection is shown in TABLE 1.1. An obvious question when using an outcome measure in practice is, ‘how much change must there be before I know my patient’s status has altered?’ The statistic of interest here is the Minimum Clinically Important Difference (MCID). MCIDs have been reported for a number of outcome measures. Some are duplicated here (TABLE 1.1), but note that these values are specific to the populations, conditions and settings in relation to which they have been obtained.

**TABLE 1.1. Examples of combined pain–function and pain outcome measures, with Minimum Clinically Important Differences (MCIDs) and references.** ¹Patients with mixed-type shoulder pain (the care setting was unclear); ²Patients with first episode of shoulder pain in primary care; ³Patients with mixed-type shoulder pain at various outpatient clinics ⁴Patients undergoing non-operative treatment in secondary care for rotator cuff disease; ⁵Chronic musculoskeletal pain in secondary care.

### 1.6. Summary of key points in diagnosis and assessment

- The principal diagnostic test is passive external rotation, which is restricted in contracted (frozen) shoulder (but also in other conditions).
- A finding of restricted passive external rotation should be corroborated by history (screening for substantial trauma/serious disease), x-ray examination (which can exclude the other causes of restriction) and palpation (screening for gross crepitus).
- Measuring the range of passive external rotation reliably is difficult, and this should be recognised. We suggest a method in standing which involves estimating range to the nearest 30°. We also suggest that operational definitions are made explicit.
- We recommend the terminology ‘pain-predominant’ and ‘stiffness-predominant’ to classify the stage of the condition. Where there is doubt, pain should take precedence.
- As a minimum, a validated region/condition-specific measure should be used to evaluate patients’ status, progress and outcome.
1.7. **An overview of treatment options**

This section gives an overview of treatment options, from advice and education to operative intervention, briefly discussing those options’ intended effects and the means by which they are supposed to achieve their effects. Emphasis is placed on the more common interventions as determined by a questionnaire survey of CSP members with 289 valid respondents (Hanchard et al 2010) and the focus of recent trials. We have organised the treatment options from more to less conservative, but the order is not meant to be prescriptive. It should not be supposed that any individual would, or should, receive all of the treatments listed. Nor are the treatments necessarily mutually exclusive.

The information for each option is arranged under **Background** and, to provide clinical context, *Results of CSP survey* (Hanchard et al 2010). The popularity or otherwise of an intervention should not be taken as evidence of efficacy.

1.7.1. **Conservative management**

**Advice and education**

*Background:* Advice and education from physiotherapists may be tailored to individuals or given in more generic form, possibly as a patient information leaflet.

Patients may be frightened by the severity of their symptoms, and may compare their experience unfavourably with that of relatives or friends who have had ‘shoulder pain’, especially if improvement seems slow. Reassurance is therefore a key factor: specifically, reassurance that serious causes of shoulder pain are rare; that the patient has been screened for potential red flags; and that the condition is usually self limiting. Simply acknowledging the severity of symptoms may help provide peace of mind, as may education on the potential spectrum and variability of symptoms in contracted (frozen) shoulder.

Advice includes activity modification in the home, at work and in sporting and leisure activities. Physiotherapists may be able to suggest alternative ways of completing tasks that do not aggravate symptoms. For example, patients may find dressing easier if they wear loose and front-fastening tops, and if they place the affected arm into the arm-hole first. In bed, and during activities that require sustained positions of the affected arm, support is important: this may be achieved by use of pillows or towels in bed, or, during activities, by building the elbow’s or forearm’s platform of support up to the level required. Advice on pacing activities, avoiding aggravating factors and managing symptoms may help to prevent disruption of social activities and/or minimise the condition’s potential impact on the patient’s quality of life.

Self-management may be enhanced by an understanding of pain mechanisms, and face to face education or recommendation of textbooks may be used to achieve this.
Results of CSP survey: Ninety-six percent of respondents said that they might use or recommend advice and education for pain-predominant contracted (frozen) shoulder; 88% said that they might use or recommend advice and education in the stiffness-predominant stage.

Supervised neglect

Background: Diercks et al (2004) describe supervised neglect as supportive therapy and pendular and active exercise within the limits of pain, and the resumption of tolerable activities, with use of anti-inflammatory or analgesic medication as required.

Results of CSP survey: Supervised neglect was not given as an option.

Superficial heat or cold

Background: Superficial heat and cold are widely used to promote repair and healing processes.

Typically, heat therapy involves the application of dry or moist hot pack to the skin through some intervening protective layer (to minimise the risk of heat damage or burns). Heat therapy is believed to reduce pain by mechanisms involving the release of endorphins. Additionally, the local warming effect may reduce stiffness in joints and spasm in muscles; and heat is thought to reduce oedema (swelling) by increasing fluid absorption from the tissues. The associated increase in blood flow is believed to improve transport of oxygen and nutrients to the tissues, while aiding the removal of waste products.

Cold may be applied in many ways and works on the principle of heat exchange. Placing a cold pack on warm skin will cause heat to be drawn away from underlying inflamed tissues, while swelling is limited by constriction (narrowing) or the capillaries. Other effects are muscle relaxation, local anaesthesia, analgesia and increased pain threshold. All these effects are usually achieved within 20–30 minutes of application, depending on body type. Apply cold packs for longer than 30 minutes risks damaging the skin or deeper tissues.

Results of CSP survey: Sixty-nine percent of respondents said that they might use or recommend superficial heat or cold for pain-predominant contracted (frozen) shoulder. Over 40% said they might use or recommend one or the other of these modalities in the stiffness-predominant stage.

Exercise therapy

Background: Exercise therapy is regularly used in the management of shoulder complaints. In the context of pain-predominant contracted (frozen) shoulder, gentle rhythmic active exercises (e.g. Codman’s pendular exercises) may help to reduce pain (pain modulation) and maintain the health of tissues within and around the joint. In the stiffness-predominant stage, function-based exercises may be used to maintain/restore the range or quality (co-ordination and/or control) of movement or both.

Results of CSP survey: Seventy-nine percent of respondents said that they might use or recommend gentle active exercise in the management of pain-predominant contracted (frozen) shoulder. Seventy-five percent said that they might use or recommend function-based exercises for stiffness-predominant contracted (frozen) shoulder.
Manual mobilisations

**Background:** Manual mobilisations (normally abbreviated to ‘mobilisations’) are therapist-applied passive movements of joints or other structures performed in such a way that they are always within the control of the patient. They may be performed by various techniques and may be combined with active movement on the part of the patient. The main aim in pain-predominant contracted (frozen) shoulder is pain relief, for which rhythmic mobilisations within comfortable range are used. It is speculated that these cause interactions between different types of nerve fibres, ‘blocking’ the transmission of pain signals to the brain. The same theory underpins the use of several electrotherapies in pain-predominant contracted (frozen) shoulder (see further). In the stiffness-predominant stage, the main aim is to restore range of movement, so mobilisations will stretch the joint into resistance.

**Results of CSP survey:** Thirty-five percent of respondents said they might use or recommend joint mobilisations for pain-predominant contracted (frozen) shoulder. Eighty-seven percent said they might use or recommend mobilisations in the stiffness-predominant stage.

Electrotherapy

**General**

**Background:** Electrotherapy includes trans-cutaneous electrical nerve stimulation (TENS), a low-cost pain-control device; interferential (IF), a therapist-applied type of nerve stimulation; and shortwave diathermy (SWD) and pulsed shortwave diathermy (PSWD), which are both forms of radio-frequency electromagnetic field. We have also included therapeutic ultrasound in this category. Ultrasound does not involve applying any currents or fields to the patient’s tissues and, in that sense, is not, strictly speaking, ‘electrotherapy’. But it is included among electrotherapy modalities by popular usage among physiotherapists and in many textbooks. (For an up to date list of electrotherapy books, see Professor Tim Watson’s website at [http://www.electrotherapy.org/index.htm](http://www.electrotherapy.org/index.htm).

**Results of CSP survey:** Electrotherapy ranked as only the tenth most preferred treatment for pain-predominant contracted (frozen) shoulder. Only 30% of all respondents chose this option: see under the individual modalities for a further breakdown. An interesting observation was that electrotherapy was substantially less popular among physiotherapists with a special interest in contracted (frozen) shoulder (22%) than those without (38%). This difference was statistically significant (Chi-square 7.780, \( p = 0.0053 \)) and highly unlikely to be due to chance alone. For stiffness-predominant contracted (frozen) shoulder, fewer than 4% of respondents chose electrotherapy of any sort as an option.

**Trans-cutaneous electrical nerve stimulation (TENS)**

**Background:** TENS consists of low frequency electrical pulses (generated by a small, portable unit) transmitted to the tissues through electrodes on the skin. The pulses stimulate peripheral nerves in such a way as to suppress the perception of pain. Different pulse patterns are believed to achieve
analgesia by different mechanisms: by causing interactions between types of nerve fibres, resulting in a ‘block’ on the transmission of pain signals to the brain; or by releasing hormones that block pain receptors in the central nervous system.

Results of CSP survey: Sixteen percent of respondents said that they might use or recommend TENS at some stage in the management of contracted (frozen) shoulder.

Interferential

Background: Low frequency electrical currents are known to have analgesic effects in the tissues (see TENS above for postulated mechanisms), but a low frequency current sufficiently strong to reach deeper tissues would be painful on the skin. Medium frequency currents are more comfortable on the skin, but lack analgesic effects in the deeper tissues. Interferential aims to circumvent this problem. In classical (or ‘four polar’ or ‘quadrupolar’) interferential, which uses four electrodes, two medium-frequency currents are applied to the skin surface in such a way that they interact in the deeper tissues, generating a low-frequency stimulus and the desired therapeutic response. Another type of interferential exists, called bipolar interferential. This differs from the traditional type in that the medium frequency currents interact within the machine, rather than the patient’s tissues. As far as is known, the two types of interferential are interchangeable in terms of their physiological effects (reviewed by Watson, 2009).

Results of CSP survey: Six percent of respondents said that they might use or recommend interferential at some stage in the management of contracted (frozen) shoulder.

Short-wave diathermy (SWD) and pulsed shortwave diathermy (PSWD)

Background: SWD is radio-frequency energy which generates heat in the tissues. The heating effect is thought to be deeper than that obtainable using, for example, hot packs or a heat lamp. However, there is still disagreement over which tissues are preferentially heated by SWD. In recent years, PSWD has become relatively more prevalent than SWD. In this mode, SWD is applied in pulses, between which heat is able to dissipate to a greater or lesser extent (depending on the intensity, the length of the pulses, and the interval between them). In general, the therapeutic effects of heating include analgesia, reduced muscle spasm, reduced joint stiffness, increased metabolism and increased blood flow, all of which could, theoretically, be beneficial at some stage or other of contracted (frozen) shoulder.

Results of CSP survey: Eight percent of respondents said that they might use or recommend SWD or PSWD at some stage in the management of contracted (frozen) shoulder.

Therapeutic ultrasound

Background: Sound is mechanical vibration and ultrasound is mechanical vibration at very high frequencies—well above the audible range. Ultrasound does have a heating effect, although, as with PSWD (see above) it may be pulsed to allow heat to dissipate, and it is uncertain whether any effects are due to thermal or non-thermal mechanisms. Theoretical benefits include those
attributed to SWD and PSWD (see above) as well as increased rate of healing and improved quality of tissue repair.

**Results of CSP survey:** Six percent of respondents said that they might use or recommend therapeutic ultrasound at some stage in the management of contracted (frozen) shoulder.

**Medication**

*Non-opioid analgesics*

**Background:** Non-opioid analgesics include aspirin and the other non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol, and are suitable for pain of musculoskeletal origin. Paracetamol differs from the NSAIDs in having no anti-inflammatory activity but being less irritating to the gastric system.

**Results of survey:** Not applicable.

*Opioid analgesics*

**Background:** The opioid analgesics, e.g. codeine, are one of the main classes of pain relieving drugs, and act on the central nervous system to increase tolerance to pain. Semi-synthetic variants include Tramadol.

**Results of survey:** Not applicable.

*Corticosteroids*

**Background:** Corticosteroids (for which the generic term ‘steroids’ is usually used) strongly suppress all stages of acute and chronic inflammation. In relation to contracted (frozen) shoulder, they may be injected directly into the joint or taken orally (in tablet form), though the latter is unusual in the UK.

**Results of CSP survey:** Twenty-four percent of respondents reported practising injection therapy, and the proportion was significantly greater among those with a special interest in shoulders (Chi-square 33.803, \( p < 0.0001 \)).

1.7.2. **Minimally invasive treatments**

**Acupuncture**

**Background:** Acupuncture can be used to treat the pain of contracted (frozen) shoulder. It involves inserting needles into the skin at sites which vary from case to case and also depending on the practitioners’ school of thought. Typically some needles will be placed near the shoulder and others distant from it. Once the patient feels some sensation at the needling sites, the needles may simply be left in place for the treatment session; in other circumstances they may be stimulated, either by manual manipulation or by small electric pulses. According to traditional theory, acupuncture restores health by removing blockages in energy force. Western explanations lean towards nerve interactions and hormonal mechanisms (see TENS and interferential).
**Results of CSP survey:** The majority of respondents (61%) reported practising acupuncture, and 68% of respondents said that they might use or recommend acupuncture for pain-predominant contracted (frozen) shoulder. Only 10% said that they might use or recommend acupuncture for stiffness-predominant contracted (frozen) shoulder.

**Injections**

*Corticosteroids*

*See above*

**Distension therapy (hydrodilation)**

**Background:** Distension therapy involves injecting large volumes of fluid (saline or local anaesthetic, with or without corticosteroid) into the shoulder joint, with the aim of distending or even rupturing the joint capsule.

**Results of CSP survey:** Not applicable.

*Sodium hyaluronate*

**Background:** Sodium hyaluronate (hyaluronic acid) can be injected into the shoulder joint to treat the pain of contracted (frozen) shoulder. It has less known potential for adverse effects than corticosteroids, and some prefer it on these grounds.

**Results of CSP survey:** Not applicable (information on use of sodium hyaluronate was not sought).

1.7.3. Operative treatments

**Arthroscopic capsular release and manipulation under anaesthetic (MUA)**

**Background:** Arthroscopic capsular release is usually reserved for patients with contracted (frozen) shoulder whose symptoms do not improve with an adequate course of physiotherapy. The procedure is normally performed in conjunction with an MUA, and may reduce the potential harms of that procedure by allowing it to be done less forcefully. Using a ‘keyhole’ technique, the surgeon divides the capsule at the front and lower part of the joint. If the patient continues to lack external rotation in abduction, the capsule can also be released at the back of the joint. In addition to a general anaesthetic, it is normal for a regional nerve block to be given. This causes post-operative numbness and enables the patient to get moving at the earliest possible stage. Intensive physiotherapy is regarded as essential to a good outcome.

**Results of CSP survey:** Not applicable.

2. Systematic review and meta-analysis of treatment interventions

This section gives an overview of the systematic review and meta-analysis of treatment interventions and concludes by enumerating the responses to the questionnaire survey. We have kept it as light and readable as possible, but it is unavoidably complex. It is derived from methodologically stringent processes which underpin our recommendations for management. If you are not interested in the methods, you may choose to skip straight to the recommendations (starting on page 63 for text, and 76 for summary table). Conversely, there are signposts throughout to more detailed information in the APPENDICES.

2.1 Results of search and filtering processes

After de-duplication our search retrieved 749 citations, most with abstracts. Primary filtering left 83 citations. The secondary filtering process excluded 64 of these (APPENDIX C: Table of excluded studies; APPENDIX D: References to table of excluded studies). Thus 19 trials remained for analysis. Most trials studied samples with mixed-stage contracted (frozen) shoulder. There were various comparisons (34 in all) of home exercises, supervised physiotherapy and pharmacological interventions (see APPENDIX B). Some of these trials were included under several interventional categories (TABLE 2.1).

**TABLE 2.2. Methodological quality of included trials.** *Analyses were adjusted for unequal distribution of gender. †Reportedly yes, but not done in analysis.

The median sample size was 80 (range 18–149; interquartile range 41–104), and about half of the trials (9/19) were of good methodological quality (low risk of bias). In the remainder there were deficiencies in random allocation (Guler-Uysal & Kozanoglu 2004), allocation concealment (Bulgen et al 1984, Calis et al 2006, Cheing, So & Chao 2008, Dacre, Beeneey & Scott 1989, Guler-Uysal & Kozanoglu 2004, Khan et al 2005, Nicholson 1985); or blinding of assessors (Calis et al 2006, Johnson et al 2007, Khan et al 2005). Each of these methodological deficiencies has been empirically linked to overestimation of treatment effects. Trials with inadequate allocation
concealment have been found to exaggerate treatment effects by around 40% on average (Moher et al 1998, Schulz et al 1995). Schulz et al (1995) have additionally shown that trials with unclear concealment methods exaggerate treatment effects by an average of 30%. Furthermore, Jüni et al (1999) found that trials with non-blinded outcome assessment exaggerate treatment effects by 35%.

2.3. Results of analyses

Our protocol did not anticipate that there would be so many comparisons in so many trials with a moderate-to-high risk of bias (TABLE 2.2). Faced with this contingency, we limited further analyses to comparisons in those trials with a low risk of bias (TABLE 2.3). These comparisons could be grouped under six main headings:

1. Physiotherapy versus other physiotherapy
2. Physiotherapy versus other treatments
3. Physiotherapy versus combinations of physiotherapy and other treatments
4. Adding physiotherapy to other treatments
5. Adding physiotherapy elements to combinations of physiotherapy and other treatments
6. Adding other treatments to physiotherapy

The trials concerned used a range of outcome measures. For dichotomous outcomes (e.g. ‘improved’/‘not improved’) we calculated the Relative Risk (RR) and its 95% confidence interval (95% CI). For outcomes measured on continuous scales we calculated the Mean Difference (MD) and its 95% CI.
### TABLE 2.3. Methodological quality of included trials: trials with moderate to high risk of bias excluded (shaded). *Analyses were adjusted for unequal distribution of gender. †Reportedly yes, but not done in analysis.

</table>

To pool trials which measured the same outcome but with different tools, e.g. SPADI and SRQ, we calculated the Standardised Mean Difference (SMD) and its 95% CI. We then converted the SMD and its 95% CIs back into the units of one of the original outcomes, since these are more meaningful clinically than the SMD (Cochrane Handbook 2009). To further enhance clinical relevance, we reported the Minimal Clinically Important Difference (MCID), if known, for all outcomes. We derived within-subject MCIDs from the research literature, but multiplied these by 0.4. We applied this adjustment because between-groups MCID (i.e. an important difference between groups, as in a controlled trial) is thought to approximate to 40% of that within individuals (Finch et al 2002). These processes allowed us to see whether the outcome and its 95% CI (a) overlapped zero and (b) overlapped the adjusted threshold for MCID on either side of zero. If the 95% CI did not overlap zero it could be stated, with 95% confidence, that the intervention had a directional effect. Furthermore, a 95% CI that lay entirely beyond the adjusted threshold for a
MCID could be said, with 95% confidence, to have a clinically important effect favouring that intervention. The comparisons are considered below.

2.3.1. Physiotherapy versus other physiotherapy

2.3.1.1. Adding outpatient physiotherapy (with passive mobilisations) to home exercises for both stages of contracted (frozen) shoulder

In subgroups totalling 46 patients, two trials evaluated the addition of outpatient physiotherapy (with passive mobilisations) to home exercises in mixed-stage contracted (frozen) shoulder in primary and secondary care (Carette et al 2003, Ryans et al 2005). Both trials adapted the passive mobilisations according to the condition’s stage. Functional outcome measures were the SPADI and SDQ respectively. Carette et al (2003) reported pain scores both as part of the composite SPADI and separately, while Ryans et al (2005) evaluated global pain using a 100 mm VAS. Both trials also evaluated passive external rotation. Neither specified adverse events as an outcome.

Assessment time points included 6 weeks (short term), 4-6 months (medium term) and, for Carette et al (2003) only, 12 months (long term).

**Functional outcome, short term (6 weeks)**

*Result:* $P = 0.59$, SMD = 0.11 [0.30, 0.53] and see FIGURE 2.1.

*Result re-expressed as SPADI:* Mean Difference (MD) = 2.70 [-7.35, 12.99].

*Adjusted threshold for MCID (calculated from data in Paul et al 2004):* 3.2.

*Interpretation:* A clinically unimportant mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether such an effect would be clinically important.

**Functional outcome, medium term (4-6 months)**

*Result:* $P = 0.80$, SMD = 0.06 [-0.39, 0.51] and see FIGURE 2.2.

*Result re-expressed as SPADI:* 1.47 [-12.50, 9.56].

*Adjusted threshold for MCID (calculated from data in Paul et al 2004):* 3.2.

*Interpretation:* The mean effect differed in direction in the two study samples, but this is of doubtful importance, since there was considerable overlap between their respective 95% CIs. This effect was not statistically significant. The 95% CI crossed zero and the threshold for
MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether such an effect would be clinically important.

### Functional outcome (SPADI), long term (12 months)

**Result:** $P = 0.82$, $MD = 1.70 [-12.78, 16.18]$.

Adjusted threshold for MCID (calculated from data in Paul et al 2004): 3.2.

**Interpretation:** A clinically unimportant mean effect favoured the home exercises only group in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether such an effect would be clinically important.

We pooled the short term and medium term results for the SPADI pain score in Carette et al (2003) with those for the 100 mm VAS for global pain in Ryans et al (2005). No long term results were reported by Ryans et al (2005).

### Pain, short term (6 weeks)

**Result:** $P = 0.23$, $SMD = 0.26 [-0.17, 0.68]$ and see FIGURE 2.3.

**Result re-expressed as 100 mm VAS:** $MD = 5.64 [-4.17, 16.66]$.

Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.

**Interpretation:** A small, clinically important mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. However, only the addition of outpatient physiotherapy had potential for a clinically important effect.

### Pain, medium term (4-6 months)

**Result:** $P = 0.39$, $SMD = 0.20 [-0.25, 0.65]$ and see FIGURE 2.4.

**Result re-expressed as 100 mm VAS:** $MD = 5.7 [-7.13, 18.53]$.

---

**FIGURE 2.2**

**FIGURE 2.3**
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.

Interpretation: A small, clinically important mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

We also pooled the short term results for improvement in passive external rotation (degrees) in Carette et al (2003) and Ryans et al (2004). No long term results were reported by Ryans et al (2005).

Pain, long term (SPADI pain score) (12 months)

Result: P = 0.99, MD = 0.10 [-15.01, 15.21]

Adjusted threshold for MCID: MCID not known.

Interpretation: There was no mean difference between groups in the study sample. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

Passive external rotation, short term (6 weeks)

Result: P = 0.03, MD = 6.68 [0.53, 12.82] and see FIGURE 2.5.

Adjusted threshold for MCID: MCID not known.

Interpretation: A small mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional effect would be anticipated in the wider population. The clinical importance of such an effect (< 13°) is uncertain.

Passive external rotation, medium term (4-6 months)

Result: P = 0.79, MD = 1.44 [-6.59, 9.48] and see FIGURE 2.6.

Adjusted threshold for MCID: MCID not known.

Interpretation: A small mean effect favoured adding outpatient physiotherapy to home
exercises in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

### Passive external rotation, long term (12 months)

**Result:** $P = 0.8$, $MD = 1.20 [-7.95, 10.35]$.

**Adjusted threshold for MCID:** MCID not known.

**Interpretation:** A small mean effect favoured adding outpatient physiotherapy to home exercises in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

#### 2.3.1.2. Home ‘muscle function retraining programme’ versus outpatient physiotherapy (with passive mobilisations) and standard home exercises for both stages of contracted (frozen) shoulder

In a subgroup of 50 patients in secondary care with mixed-stage contracted (frozen) shoulder, Ginn and Cohen (2005) compared an individualised programme of home exercises (a ‘muscle function retraining programme’) to a combination of outpatient physiotherapy (with passive mobilisations) and standard home exercises. Outcomes were assessed at 5 weeks (short term) only and included patients’ global perceptions of change: ‘improved’, ‘stable’ or ‘deteriorated’. No subgroup-specific results were reported for pain, and passive external rotation was not among the outcome measures. Adverse effects were reported.

**Patients’ global perception of change, short term (5 weeks)**

We pooled the ‘stable’ and ‘deteriorated’ categories, and compared these to the ‘improved’ category for analysis.

**Result:** $P = 0.25$, RR = 0.84 [0.62, 1.14].

**Adjusted threshold for MCID:** Not applicable (dichotomous outcome).

**Interpretation:** A small mean effect favoured adding outpatient physiotherapy to home exercises in the study sample. This effect was not statistically significant. The 95% CI crossed one. Thus it is uncertain in which direction (if any) an effect would occur in the population.

**Adverse effects, short term (5 weeks)**
Result: One subject in the muscle function retraining programme group (1/24 = 4%) and one in the outpatient physiotherapy and standardised home exercise group (1/26 = 4%) experienced deterioration over the 5 week study period. No further details were given.

2.3.1.3. High grade mobilisations versus low grade mobilisations for stiffness-predominant contracted (frozen) shoulder

In a trial of 100 patients with stiffness-predominant contracted (frozen) shoulder in secondary care, Vermeulen et al (2006) compared a package of physiotherapy including high grade mobilisations to a similar package containing low grade mobilisations. Outcomes were assessed at 3 months (short term), 6 months (medium term) and 12 months (long term). Outcomes included the SRQ; pain during movement, at rest, and at night, recorded on a VAS; passive external rotation measured using a goniometer; and adverse events. Regarding the latter, participants’ opinions on their shoulder function relative to baseline were sought, but the ‘much worse’, ‘worse’ and ‘no change’ categories were combined in the report’s Results section.

**SRQ, short term (3 months)**

Result: P = 0.75, MD = 2.00 [-10.07, 14.07].

Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.2.

Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

**SRQ, medium term (6 months)**

Result: P = 0.20, MD = 4.50 [-2.40, 11.40].

Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.2.

Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of high grade mobilisations

**SRQ, long term (12 months)**

Result: P = 0.07, MD = 6.60 [-0.61, 13.81].

Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.2.

Interpretation: A clinically important mean effect favoured high grade mobilisations in the study sample. This effect fell short of significance statistically. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of high grade mobilisations.

**100 mm VAS for night pain, 3 months (short term)**

Result: P = 0.58, MD = 3.80 [-9.75, 17.35]

Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.

Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the
threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for night pain, 6 months (medium term)
Result: P = 0.58, MD = 7.10 [-7.10, 21.30].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically important mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for night pain, 12 months (long term)
Result: P = 0.23, MD = 7.80 [-4.91, 20.51].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of high grade mobilisations.

100 mm VAS for pain at rest, 3 months (short term)
Result: P = 0.2, MD = 7.10 [-3.70, 17.90].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured low grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of low grade mobilisations.

100 mm VAS for pain at rest, 6 months (medium term)
Result: P = 0.74, MD = 2.00 [-9.74, 13.74]
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured low grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for pain at rest, 12 months (long term)
Result: P = 0.87, MD = 0.90 [-9.88, 11.68].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured low grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for pain on use, 3 months (short term)
Result: P = 0.65, MD = 2.60 [-8.46, 13.66]
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for pain on use, 6 months (medium term)
Result: \( P = 0.93, \text{MD} = 0.50 [-10.19, 11.19] \).
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for pain on use, 12 months (long term)
Result: \( P = 0.26, \text{MD} = 6.60 [-4.99, 18.19] \).
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of high grade mobilisations.

Passive external rotation, short term (3 months)
Result: \( P = 0.58, \text{MD} = 1.40 [-3.50, 6.30] \).
Adjusted threshold for MCID: MCID not known.
Interpretation: A small mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

Passive external rotation, medium term (6 months)
Result: \( P = 0.12, \text{MD} = 4.10 [-1.03, 9.23] \).
Adjusted threshold for MCID: MCID not known.
Interpretation: A small mean effect favoured high grade mobilisations in the study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

Passive external rotation, long term (12 months)
Result: \( P = 0.04, \text{MD} = 6.50 [0.27, 12.73] \).
Adjusted threshold for MCID: MCID not known.
Interpretation: The mean effect favoured high grade mobilisations in the study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional effect would be anticipated in the population. The clinical importance of such an effect (< 13°) is uncertain.
2.3.1.4. High grade mobilisations and home exercises versus MWMs and home exercises for both stages of contracted (frozen) shoulder

Yang et al (2007) divided patients 27 between A-B-A-C and A-C-A-B groups, where A was mid-range mobilisation, B, end-range mobilisation and C mobilisations with movement (MWMs). We considered that only the second phases (B versus C) constituted a randomised controlled trial, since phases 1 and 3 were unrandomised and allocation in phase 4 was predictable. The outcome was the Flexi-level Scale of Shoulder Function (FLEX-SF), which was assessed at baseline and after each 3-week phase of the trial. Of relevance here was the measurement at 6 weeks (short term), comparing end-range mobilisations and home exercises with MWMs and home exercises.

**Flexi-level Scale of Shoulder Function (FLEX-SF), short term (6 weeks)**

Result: P = 0.5, MD 1.9 [-3.61, 7.41].

Interpretation: A clinically important mean effect favoured MWMs in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

2.3.1.5. Adding SWD to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder

One trial of stiffness-predominant contracted (frozen) shoulder, with 10 patients per subgroup, (Leung & Cheing 2008) added shortwave diathermy (SWD) to a combination of outpatient physiotherapy (supervised stretching exercises without passive mobilisations) and home stretching exercises. Outcome measures were assessed at 8 weeks (short term) and included the patient-completed section of the ASES, which is intended to measure pain and functional limitation. (The physician-completed section of the ASES was also used. This involves measuring range of movement, and data for external rotation were separately reported; but it is unclear was whether these related to passive or active range.)

**Patient-completed section of ASES, short term (8 weeks)**

Result: P = 0.03, MD = 17.50 [1.76, 33.24].

Adjusted threshold for MCID (calculated from data in Michener, McClure & Sennett 2002): 2.56.

Interpretation: A mean clinically important effect favoured adding SWD in the study sample. The result was statistically significant. The 95% CI lay on the side of zero that favoured SWD, so an effect in this direction would be expected in the population. Moreover, almost all of the 95% CI exceeded the threshold for MCID, so a clinically important effect might tentatively be anticipated.
2.3.1.6. **Adding hot packs to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder**

In the same trial, Leung and Cheing (2008) added hot packs to a combination of outpatient physiotherapy (supervised stretching exercises without passive mobilisations) and home stretching exercises.

*Patient-completed section of ASES, short term (8 weeks)*

*Result:* $P = 0.59$, $MD = 4.00$ [-10.38, 18.38].

*Adjusted threshold for MCID (calculated from data in Michener, McClure & Sennett 2002):* 2.56.

*Interpretation:* A clinically important mean effect favoured hot packs in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

2.3.1.7. **Outpatient physiotherapy (SWD and exercises) and home exercises versus outpatient physiotherapy (heat pack and exercises) and home exercises for stiffness-predominant contracted (frozen) shoulder**

The study considered above (Leung & Cheing 2008) also conducted a head-to-head comparison of outpatient physiotherapy (SWD and exercises) and home exercises versus outpatient physiotherapy (heat pack and exercises) and home exercises.

*Patient-completed section of ASES, short term (8 weeks)*

*Result:* $P = 0.09$, $MD = 13.50$ [-2.16, 29.16].

*Adjusted threshold for MCID (calculated from data in Michener, McClure & Sennett 2002):* 2.56.

*Interpretation:* A clinically important mean effect favoured SWD over hot packs in the study sample. The result was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of SWD.

2.3.2. Physiotherapy versus other treatments

2.3.2.1. **Outpatient physiotherapy (with mobilisations) versus an intra-articular steroid injection for both stages of contracted (frozen) shoulder**

One trial of 109 patients in primary care, probably with mixed-stage contracted (frozen) shoulder, compared out-patient physiotherapy (with mobilisations) versus steroid injections (van der Windt et al 1998). Outcome measures included the 16-item SDQ; 100-point VAS for day and night pain and improvement in passive range of external rotation, with assessment time-points including 7 weeks (short term), 6½ months (medium term) and 12 months (long term). Adverse events were recorded by the clinician and by patients on their own forms.
Improvement in 16-item SDQ, short term (7 weeks)
Result: P = 0.00001, MD = 25.00 [14.81, 35.19].
Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.6.
Interpretation: A clinically important mean effect favoured steroid injection in the study sample. This effect was highly statistically significant and, based on the 95% CI, a similarly directional, and clinically important, effect would be anticipated in the population.

Improvement in 16-item SDQ, medium term (6½ months)
Result: P = 0.1, MD = 10.00 [-1.88, 21.88].
Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.6.
Interpretation: A clinically important mean effect favoured steroid injection in the study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of steroid injection.

Improvement in 16-item SDQ, long term (12 months)
Result: P = 0.54, MD = 4.00 [-8.64, 16.64].
Adjusted threshold for MCID (calculated from data in Paul et al 2004): 5.6.
Interpretation: A clinically important mean effect favoured steroid injection in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for night pain, short term (7 weeks)
Result: P = 0.01, MD = 14.00 [3.06, 24.94].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically important effect favoured steroid injection in the study sample. This effect was statistically significant. The 95% CI lay on the side of zero that favoured steroid injection, so an effect in this direction would be expected in the population; but as the CI crossed the threshold for MCID, it is unclear whether this effect would be clinically important.

100 mm VAS for night pain, medium term (6½ months)
Result: P = 0.89, MD = 1.00 [-13.53, 15.53].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: There was no substantive mean effect in the study sample. There was no statistically significant difference. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for night pain, long term (12 months)
Result: P = 0.77, MD = 2.00 [-11.59, 15.59].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured steroid injection in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the
threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for day pain, short term (7 weeks)
Result: \(P = 0.005\), MD = 12.00 [3.69, 20.31].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically important mean effect favoured steroid injection in the study sample. This effect was statistically significant. The 95% CI lay on the side of zero that favoured steroid injection, so an effect in this direction would be expected in the population; but as the CI crossed the threshold for MCID, it is unclear whether this effect would be clinically important.

100 mm VAS for day pain, medium term (6½ months)
Result: \(P = 1.0\), MD = 0.00 [-10.00, 10.00].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: There was no mean difference between groups in the study sample. The result was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

100 mm VAS for day pain, long term (12 months)
Result: \(P = 0.52\), MD = 3.00 [-6.24, 12.24].
Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.
Interpretation: A clinically unimportant mean effect favoured steroid injection in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

Improvement in passive external rotation, short term (5 weeks)
Result: \(P < 0.00001\), MD = 15.00 [9.31, 20.69]
Adjusted threshold for MCID: MCID not known.
Interpretation: The mean effect favoured steroid injection in the study sample. This effect was highly statistically significant. Based on the 95% CI, a similarly directional effect would be expected in the population. The clinical importance of such an effect (< 21°) is uncertain.

Improvement in passive external rotation, medium term (6½ months)
Result: \(P = 0.02\), MD = 9.00 [1.64, 16.36]
Adjusted threshold for MCID: MCID not known.
Interpretation: The mean effect favoured steroid injection in the study sample. This effect was statistically significant. Based on the 95% CI, a similarly directional effect would be expected in the population. The clinical importance of such an effect (< 16°) is uncertain.

Adverse events
Fifty-three percent of the injection group, and 56% of the physiotherapy group, reported adverse events. (Note that, in a deviation from protocol, 5 patients were treated with both interventions.) These adverse events were minor, and included: pain lasting a day or less
after treatment (9 patients in the injection group; 17 patients in the physiotherapy group); pain lasting 2 days or more after treatment (16 patients in the injection group; 13 patients in the physiotherapy group); facial flushing (9 patients in the injection group; 1 patient in the physiotherapy group); irregular menstruation (2 patients in the injection group); self-diagnosed fever (2 patients in the injection group; 1 patient in the physiotherapy group); skin irritation (1 patient in the injection group; 2 patients in the physiotherapy group); and other events, including sweating, fatigue, dry mouth, dizziness and headache (6 patients in the injection group), and slight swelling, tingling and radiating pain (4 patients in the physiotherapy group).

2.3.2.2. Home muscle function retraining programme versus a subacromial steroid injection for both stages of contracted (frozen) shoulder

In a subgroup of 45 patients with mixed-stage contracted (frozen) shoulder in secondary care, Ginn and Cohen (2005) compared an individualised programme of home exercises (a ‘muscle function retraining programme’) to a subacromial steroid injection. Outcomes were assessed at 5 weeks (short term) and included patients’ global perceptions of change: ‘improved’, ‘stable’ or ‘deteriorated. No subgroup-specific results were reported for pain, and passive external rotation was not among the outcome measures. Adverse effects were reported.

Patients’ global perception of change, short term (5 weeks)
We pooled the ‘stable’ and ‘deteriorated’ categories, and compared these to the ‘improved’ category for analysis.
Result: $P = 0.79$, $RR = 0.96 \ [0.69, 1.33]$.
Adjusted threshold for MCID: MCID not known.
Interpretation: There was no substantive difference between groups and none would be inferred to the population.

Adverse events, short term (5 weeks)
One patient in the muscle function retraining programme group (1/24 = 4%) and one in the subacromial injection group (1/22 = 5%) experienced deterioration. No further details were given.

2.3.2.3. Outpatient physiotherapy (with passive mobilisations) and home exercises versus a subacromial steroid injection for both stages of contracted (frozen) shoulder

Ginn and Cohen (2005) compared a combination of outpatient physiotherapy (with passive mobilisations) and standard home exercises against a subacromial steroid injection in a subgroup of 48 patients with mixed-stage contracted (frozen) shoulder in secondary care. Outcomes were assessed at 5 weeks (short term) and included patients’ global perceptions of change: ‘improved’, ‘stable’ or ‘deteriorated. No subgroup-specific results were reported for pain, and passive external rotation was not among the outcome measures. Adverse effects were reported.
Patients’ global perception of change, short term (5 weeks)

We pooled the ‘stable’ and ‘deteriorated’ categories, and compared these to the ‘improved’ category for analysis.

Result: \( P = 0.52, \text{RR} = 1.10 \ [0.83, 1.45] \)

Adjusted threshold for MCID: MCID not known.

Interpretation: There was no substantive difference between groups, and none would be inferred to the population.

Adverse effects, short term (5 weeks)

Result: One patient in the outpatient physiotherapy and home exercises group (1/26 = 4%), and one in the subacromial injection group (1/22 = 5%) experienced deterioration. No further details were given.

2.3.3. Physiotherapy versus combinations of physiotherapy and other treatments

2.3.3.1. Outpatient physiotherapy (with passive mobilisations) and home exercises versus steroid injections and home exercises for both stages of contracted (frozen) shoulder

We pooled the results of two trials (Carette et al 2003, Ryans et al 2005), with a combined sample size of 88 for the relevant subgroups, which compared outpatient physiotherapy (with passive mobilisations) and home exercises to an intra-articular steroid injection and home exercises for mixed-stage contracted (frozen) shoulder in primary and secondary care. The functional outcome in Carette et al (2003) was the Shoulder Pain and Disability Index (SPADI) and that in Ryans et al (2005) was the 22-point Shoulder Disability Questionnaire (SDQ); Carette et al (2003) reported the SPADI score for pain as part of the composite outcome but also separately, whereas Ryans et al (2005) scored global pain on a 100 mm VAS. Both trials evaluated passive external rotation. Neither reported adverse events as an outcome.

Assessment time points included 6 weeks (short term), 4-6 months (medium term) and, for Carette et al (2003) only, 12 months (long term).

Functional outcome, short term (6 weeks)

Result: \( P = 0.02, \text{SMD} = 0.52 \ [0.10, 0.95] \) and see FIGURE 2.7.

Result re-expressed as SPADI: \( \text{MD} = 12.74 \ [2.45, 23.28] \).

Adjusted threshold for MCID (calculated from data in Paul et al 2004): 3.2.

Interpretation: A clinically important mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was statistically significant. The 95% CI lay on the side of zero that favoured the addition of outpatient physiotherapy, so an effect in this direction would be expected in the population. Moreover, almost all of the 95% CI exceeded the threshold for MCID, so a clinically important effect favouring the addition of outpatient physiotherapy might tentatively be anticipated.
Functional outcome, medium term (4-6 months)

Result: $P = 0.13$, SMD = 0.34 [-0.11, 0.79].

Result re-expressed as SPADI: 8.33 [-2.70, 19.36].

Adjusted threshold for MCID (calculated from data in Paul et al. 2004): 3.2.

Interpretation: A clinically unimportant mean effect favoured high grade mobilisations in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of steroid injection.

Functional outcome (SPADI), long term (12 months)

Result: $P = 0.51$, MD = 4.60 [-9.13, 18.33].

Adjusted threshold for MCID (calculated from data in Paul et al. 2004): 3.2.

Interpretation: A clinically unimportant mean effect favoured the steroid injection group in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

We pooled the results for the SPADI pain score in Carette et al. (2003) with those for the 100 mm VAS for global pain in Ryans et al. (2005). No long term results were reported by Ryans et al. (2005).

Pain, short term (6 weeks)

Result: $P = 0.08$, SMD = 0.38 [-0.04, 0.81] and see FIGURE 2.9.

Result re-expressed as 100 mm VAS: MD = 9.69 [-1.02, 20.66].

Adjusted threshold for MCID (calculated from data in Tashjian et al. 2009): 5.5 mm.

Interpretation: A clinically important mean effect favoured adding outpatient physiotherapy to home exercises in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of outpatient physiotherapy.
FIGURE 2.9

**Pain, medium term (4-6 months)**

*Result:* $P = 0.70$, SMD = 0.12 [-0.75, 0.51] and see FIGURE 2.10.

*Result re-expressed as 100 mm VAS:* 3.30 [-20.63, 14.03].

*Adjusted threshold for MCID (calculated from data in Tashjian et al 2009):* 5.5 mm.

*Interpretation:* The mean effect differed in direction across the two trials, although there was considerable overlap between the respective 95% CIs. The pooled 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

FIGURE 2.10

**Pain, long term (SPADI pain score) (12 months)**

*Result:* $P = 0.40$, MD = 6.50 [-8.61, 21.61].

*Adjusted threshold for MCID: MCID not known.*

*Interpretation:* The mean effect favoured steroid injection in the study sample. This effect was not statistically significant. Thus it is uncertain in which direction (if any) an effect would occur in the population.

We also pooled the results for improvement in passive external rotation in the short term and medium term. No long term results were reported by Ryans et al (2005).

**Passive external rotation, short term (6 weeks)**

*Result:* $P = 0.58$, MD = 3.11 [-7.77, 13.99] and see FIGURE 2.11.

*Adjusted threshold for MCID: MCID not known.*

*Interpretation:* The mean effect differed in direction across the two trials, although there was considerable overlap between the respective 95% CIs. The pooled 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.
Passive external rotation, medium term (4-6 months)

Result: $P = 0.22$, $MD = 4.61 [-2.77, 12.00]$ and see FIGURE 2.12.

Adjusted threshold for MCID: MCID not known.

Interpretation: The mean effect favoured steroid injection in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

---

Passive external rotation, long term (12 months)

Result: $P = 0.82$, $MD = 0.80 [-5.98, 7.58]

Adjusted threshold for MCID: MCID not known.

Interpretation: There was no substantive mean difference between groups in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.
2.3.4. Adding physiotherapy to other treatments

2.3.4.1. Adding outpatient physiotherapy (with mobilisations) and home exercises to distension for both stages of contracted (frozen) shoulder

One trial of 149 patients in primary and secondary care with mixed-stage contracted (frozen) shoulder evaluated the effect of adding a package of outpatient physiotherapy (with passive mobilisations) and home exercises to arthrographic distension (Buchbinder et al 2007). Outcomes included SPADI; pain scores on a 10-point Likert scale, assessed globally, at night, at rest and on use; and adverse events by open-ended questions. Assessment points included six weeks (short term) and six and a half months (medium term).

**SPADI, short term (6 weeks)**
Result: P = 0.89, MD = 0.50 [-6.60, 7.60].
Adjusted threshold for MCID (calculated from data in Paul et al 2004): 3.2.
*Interpretation*: There was no substantive mean difference between groups in the study sample. This result was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

**SPADI, medium -term (6½ months)**
Result: P = 0.52, MD = 2.40 [-4.89, 9.69]
Adjusted threshold for MCID (calculated from data in Paul et al 2004): 3.2.
*Interpretation*: A clinically unimportant effect favoured the distension-only group in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

**Global pain, 10-point Likert scale, short term (6 weeks)**
Result: P = 1.00, MD = 0.00 [-0.69, 0.69]
Adjusted threshold for MCID: MCID not known.
*Interpretation*: There was no mean difference between groups in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

**Global pain, 10-point Likert scale, medium -term (6½ months)**
Result: P = 0.81, MD = 0.10 [-0.73, 0.93].
Adjusted threshold for MCID: MCID not known.
*Interpretation*: There was no substantive mean difference between groups in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

**Pain at night, at rest and on use, short term (6 weeks) and medium term (6½ months)**
As in the preceding pain comparisons, mean differences between groups were either absent or trivial and the 95% CIs were equally uninformative.
2.3.4.2. Adding out-patient physiotherapy (with passive mobilisations) to NSAIDs for both stages of contracted (frozen) shoulder

One trial of 122 patients in secondary care with mixed-stage contracted (frozen) shoulder compared outpatient physiotherapy (with passive mobilisations) versus NSAIDs (Pajareya et al 2004). Outcomes included the SPADI and range of external rotation (but it was unclear whether this was passive or active), which were assessed at 3 weeks (short term), and adverse events. Regarding the latter, the physiotherapy group were asked (a) whether or not they experienced pain for > 2 hours after treatment and (b) whether they had more disability next morning; and all patients were asked by a blinded rater ‘Have the trial drugs and/or treatment programme upset you in any way?’ and examined for signs of bruises or burns during evaluation of movement.

**SPADI, short term (3 weeks)**

*Result:* P = 0.002, MD = 8.60 [3.28, 13.92].

*Adjusted threshold for MCID (calculated from data in Paul et al 2004):* 3.2.

*Interpretation:* A clinically important effect favoured physiotherapy in the study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional, and clinically important, effect would be anticipated in the population.

**Adverse effects, short term (3 weeks)**

*Result:* Four patients reported, in total, 10 episodes of pain lasting > 2 hours after physiotherapy. Fifteen patients (12.6%) in the NSAIDs group reported gastrointestinal side-effects. Six of these had to stop taking NSAIDs due to severe dyspepsia. Two reported severe oedema (site not specified) and one a severe headache which quickly resolved when the drug treatment was discontinued.

2.3.5. Adding physiotherapy elements to combinations of physiotherapy and other treatments

2.3.5.1. Adding outpatient physiotherapy (with mobilisations) to steroid injection and home exercises for both stages of contracted (frozen) shoulder

We pooled the results of two trials (Carette et al 2003, Ryans et al 2005), with a combined sample size of 83 for the relevant subgroups, which evaluated the effect of adding outpatient physiotherapy (with mobilisations) to a package of intra-articular steroid injection and home exercises for mixed-stage contracted (frozen) shoulder in primary and secondary care. The functional outcome in Carette et al (2003) was the SPADI and that in Ryans et al (2005) was the 22-point SDQ; Carette et al (2003) reported the SPADI score for pain as part of the composite outcome but also separately, whereas Ryans et al (2005) scored global pain on a 100 mm VAS. Both trials evaluated passive external rotation. Neither reported adverse events as an outcome.

Assessment time points included 6 weeks (short term), 4-6 months (medium term) and, for Carette et al (2003) only, 12 months (long term).

**Functional outcome, short term (6 weeks)**

*Result:* P = 0.13, SMD = 0.34 [-0.10, 0.77] and see FIGURE 2.13.
**Result re-expressed as SPADI:** 3.15 [-2.43, 18.67].

**Adjusted threshold for MCID (calculated from data in Paul et al 2004):** 3.2.

**Interpretation:** A clinically unimportant mean effect favoured the addition of outpatient physiotherapy in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of outpatient physiotherapy.

**Functional outcome, medium-term (4-6 months)**

**Result:** $P = 0.13$, SMD = 0.02 [-0.44, 0.47] and see FIGURE 2.14.

**Adjusted threshold for MCID (calculated from data in Paul et al 2004):** 3.2.

**Interpretation:** The mean effects were in different directions in the two study samples, but very small (neither approached clinical importance) and there was near complete overlap of the respective 95% CIs. The pooled 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

**Functional outcome (SPADI), long term (12 months)**

**Result:** $P = 0.81$, MD = 1.80 [-16.22, 12.62].

**Adjusted threshold for MCID (calculated from data in Paul et al 2004):** 3.2.

**Interpretation:** A clinically unimportant mean effect favoured the addition of outpatient physiotherapy in the study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

We pooled the results for the SPADI pain score in Carette et al (2003) with those for the 100 mm VAS for global pain in Ryans et al (2005).
Pain, short term (6 weeks)

Result: \( P = 0.08, \text{SMD} = 0.39 [0.05, 0.82] \) and see FIGURE 2.15.

Result re-expressed as 100 mm VAS: \( \text{MD} = 8.19 [-1.05, 17.22] \).

Adjusted threshold for MCID (calculated from data in Tashjian et al 2009): 5.5 mm.

Interpretation: A clinically important mean effect favoured the addition of outpatient physiotherapy in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of outpatient physiotherapy.

Passive external rotation, long term (12 months)

Result: P = 0.15, MD = 7.20 [-2.51, 16.91].

Adjusted threshold for MCID: MCID not known.

Interpretation: A small effect favoured the addition of outpatient physiotherapy in the study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.
2.3.6. Adding other treatments to physiotherapy

2.3.6.1. Adding steroid injection to outpatient physiotherapy (with mobilisations) and home exercises for both stages of contracted (frozen) shoulder

We pooled the results of two trials (Carette et al 2003, Ryans et al 2005), with a combined sample size of 84 for the relevant subgroups, which evaluated the effect of adding an intra-articular steroid injection to a package of outpatient physiotherapy (with passive mobilisations) and home exercises for mixed-stage contracted (frozen) shoulder in primary and secondary care. The functional outcome in Carette et al (2003) was the SPADI and that in Ryans et al (2005) was the 22-point SDQ; Carette et al (2003) reported the SPADI score for pain as part of the composite outcome but also separately, whereas Ryans et al (2005) scored global pain on a 100 mm VAS. Both trials evaluated passive external rotation. Neither reported adverse events as an outcome.

Assessment time points included 6 weeks (short term), 4-6 months (medium term) and, for Carette et al (2003) only, 12 months (long term).

**Functional outcome, short term (6 weeks)**

*Result:* $P = 0.0001$, SMD = 0.89 [0.45, 1.34] and see FIGURE 2.19.

*Result re-expressed as SPADI:* 21.36 [10.80, 32.16].

*Adjusted threshold for MCID (calculated from data in Paul et al 2004):* 3.2.

**Interpretation:** A clinically important mean effect favoured the addition of steroid injection in the pooled study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional, and clinically important, effect would be anticipated in the population.

Heterogeneity: Chi² = 0.17, df = 1 ($P = 0.69$); $I^2 = 0$

Test for overall effect: $Z = 3.93$ ($P < 0.0001$)

**FIGURE 2.19**

**Functional outcome, medium term (4-6 months)**

*Result:* $P = 0.11$, SMD = 0.36 [-0.08, 0.80] and see FIGURE 2.20.

*Result re-expressed as SPADI:* 8.64 [-1.92, 19.20].

*Adjusted threshold for MCID (calculated from data in Paul et al 2004):* 3.2.

**Interpretation:** A clinically important mean effect favoured the addition of steroid injection in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect was in the direction of steroid injection.
Functional outcome (SPADI), long term (12 months)

Result: \( P = 0.7, \text{MD} = 2.80 [-11.22, 16.82] \)

Adjusted threshold for MCID (calculated from data in Paul et al. 2004): 3.2.

Interpretation: A clinically unimportant mean effect favoured the addition of steroid injection in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.

We pooled the results for the SPADI pain score in Carette et al. (2003) with those for the 100 mm VAS for global pain in Ryans (2005). No long term results were reported by Ryans et al. (2005).

Pain, short term (6 weeks)

Result: \( P = 0.29, \text{SMD} = 0.75 [0.31, 1.19] \) and see FIGURE 2.21.

Result re-expressed as 100 mm VAS: MD = 16.88 [6.98, 26.78].

Adjusted threshold for MCID (calculated from data in Tashjian et al. 2009): 5.5 mm.

Interpretation: A clinically important mean effect favoured the addition of steroid injection in the pooled study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional, and clinically important, effect would be anticipated in the population.

Pain, medium term (4-6 months)

Result: \( P = 0.54, \text{MD} = 0.14 [-0.30, 0.58] \) and see FIGURE 2.22.

Result re-expressed as 100 mm VAS: 3.85 [-8.25, 15.95].

Adjusted threshold for MCID (calculated from data in Tashjian et al. 2009): 5.5 mm.

Interpretation: The mean effect differed in direction across the two trials, although there was considerable overlap between the respective 95% CIs. The pooled 95% CI crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such an effect would be clinically important.
Pain, long term (SPADI pain score) (12 months)
Result: $P = 0.40$, MD = 6.50 [-8.61, 21.61].

Adjusted threshold for MCID: MCID not known.

Interpretation: The mean effect favoured steroid injection in the study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

We also pooled the results for improvement in passive external rotation in the short and medium term. No long term results were reported by Ryans et al (2005).

Passive external rotation, short term (6 weeks)
Result: $P = 0.002$, MD = 10.48 [-3.87, 17.09] and see FIGURE 2.23.

Adjusted threshold for MCID: MCID not known.

Interpretation: The mean effect favoured the addition of steroid injection in the pooled study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional effect would be anticipated in the population. The clinical importance of such an effect (< 18°) is uncertain.

Passive external rotation, medium term (4-6 months)
Result: $P = 0.05$, MD = 7.40 [-0.05, 14.76] and see FIGURE 2.24.

Adjusted threshold for MCID: MCID not known.

Interpretation: The mean effect favoured the addition of steroid injection in the pooled study sample. This effect was statistically significant and, based on the 95% CI, a similarly directional effect would be anticipated in the population. The clinical importance of such an effect (< 15°) is uncertain.
Passive external rotation, long term (12 months)

Result: $P = 0.18$, $MD = 6.40 [-3.04, 15.84]$.

Adjusted threshold for MCID: MCID not known.

Interpretation: The mean effect favoured the addition of steroid injection in the pooled study sample. This effect was not statistically significant. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

2.3.6.2. Adding MUA to home exercises for both stages of contracted (frozen) shoulder

One trial of 125 patients in secondary care with mixed-stage contracted (frozen) shoulder evaluated the effects of adding MUA to home exercises (Kivimäki et al 2007). Outcomes included a modified SDQ (2 questions were omitted from the standard 16-point questionnaire), pain intensity on an 11-point scale and passive external rotation. Adverse events in individuals were not specified as outcomes. Assessments were undertaken short term (6 weeks), medium term (6 months) and long term (12 months).

Modified SDQ, short term (6 weeks)

Result (as reported): $MD = 0.30 [-1.7, 2.3]$.

Adjusted threshold for MCID: MCID not known.

Interpretation: A small mean effect favoured the addition of MUA in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

Modified SDQ, medium term (6 months)

Result (as reported): $MD = 0.30 [-2.75, 2.69]$.

Adjusted threshold for MCID: MCID not known.

Interpretation: A small mean effect favoured the exercises-only group in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

Modified SDQ, medium term (6 months)

Result (as reported): $MD = 0.30 [-2.75, 2.69]$.

Adjusted threshold for MCID: MCID not known.

Interpretation: A small mean effect favoured the exercises-only group in the study sample. The 95% CI crossed zero. Thus it is uncertain in which direction (if any) an effect would occur in the population.

Pain on 11-point NPRS, short term (6 weeks)

Result (as reported): $MD = 0.20 [-0.64, 1.02]$. 

**Interpretation:** There was no substantive mean effect in the study sample. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect (and this was only marginal) was in the direction of exercises-only.

**Pain on 11-point NPRS, medium-term (6 months)**

Results (as reported): MD = 0.80 [-0.20, 1.80].

**Interpretation:** There was no substantive mean effect in the study sample. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect (and this was only marginal) was in the direction of MUA plus exercises.

**Pain on 11-point NPRS, long term (12 months)**

Results (as reported): MD = 0.7 [-0.4, 1.80].

**Interpretation:** There was no substantive mean effect in the study sample. The 95% CI crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population. The only potential for a clinically important effect (and this was only marginal) was in the direction of MUA plus exercises.

**Passive external rotation, short term**

Results (as reported): MD = 5 [-2, 12].

Adjusted threshold for MCID: MCID not known.

**Interpretation:** A small mean effect, which was probably not clinically important, favoured the MUA group. The 95% CI was uninformative in respect of inferences to the population.

**Passive external rotation, medium term**

Results (as reported): MD = 6 [-2, 14].

Adjusted threshold for MCID: MCID not known.

**Interpretation:** A small mean effect, which was probably not clinically important, favoured the MUA group. The 95% CI was uninformative in respect of inferences to the population.

**Passive external rotation, long term**

Results (as reported): MD = 4 [-4.2, 12.2].

Adjusted threshold for MCID: MCID not known.

**Interpretation:** A small mean effect, which was probably not clinically important, favoured the MUA group. The 95% CI was uninformative in respect of inferences to the population.

2.4. Results of questionnaire survey of CSP members

There were 289 valid responses. A full report is published elsewhere (Hanchard et al 2010).
2.5. References to Part 2

3. Recommendations for management of contracted (frozen) shoulder

Our recommendations for management of contracted (frozen) shoulder by ‘standard physiotherapy’ are set out and justified below. The process has, in some cases, involved comparison with other treatments (which will be the focus of future modules).

The justifications take account of the respective trials’ results (see section 3), their risk of bias (we have only included RCTs and, moreover, only those RCTs with a low risk of bias) and their GRADE quality assessments. Over and above risk of bias, GRADE quality assessments consider the following factors:

- inconsistency (which occurs when trials’ results do not agree);
- indirectness (which occurs when the trials’ results are inapplicable to the population of interest);
- imprecision (which occurs when the estimates of effect are wide); and
- publication bias (underestimation or overestimation of effects due to selective publication of studies).

An evidence quality grading: ‘high’, ‘moderate’, ‘low’ or ‘very low’ is given accordingly, and influences the strength of the recommendation.

The GRADE quality assessment and summaries of the included trials’ findings are tabulated in APPENDIX E.

3.1. Physiotherapy versus other physiotherapy

3.1.1. In primary and secondary care, should we add outpatient physiotherapy (with passive mobilisations) to home exercises for both stages of contracted (frozen) shoulder?

Settings: Secondary care in Canada, primary care in Northern Ireland.

Synthesis: The overall (modal) quality of the evidence varied by outcome, from low (combined pain–function outcomes and pain outcomes) to high (passive external rotation).

Based on low quality evidence, the short term effect on the combined pain–function outcomes was equivocal, crossing zero and the threshold for Minimum Clinically Important
Difference (MCID) on either side of zero. It was therefore unclear in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important. The evidence for short term pain outcomes was also of low quality. Although the 95% CI crossed zero, it only crossed the threshold for MCID on the side favouring the addition of outpatient physiotherapy. This means that in the population, the only potential for a clinically important difference would favour the addition of outpatient physiotherapy. Based on high quality evidence, a directional effect on passive external rotation would favour the addition of physiotherapy in the population. However, the MCID of this outcome is not known, and its importance to patients is questionable.

In the medium and long term, it was unclear in which direction (if any) an effect on combined pain–function outcomes (low quality evidence), pain outcomes (low quality evidence) and passive external rotation (high quality evidence) would occur in the population, and whether any such effects would be clinically important.

Potential harms of mechanical therapy include temporary aggravation of symptoms and would be common to both interventions, but adverse events were not listed among the outcomes in either trial’s report.

**Summary of evidence:** There is moderate-to-low quality evidence that adding outpatient physiotherapy (including passive mobilisations, and modified according to the stage of the condition) reduces pain and improves passive external rotation in the short term. No data were provided on adverse events, but these would be expected to be temporary, minor and common to both groups.

**Recommendation:** Probably add outpatient physiotherapy (with passive mobilisations) to home exercises for both stages of contracted (frozen) shoulder in primary and secondary care.

3.1.2. In secondary care, which should we use for both stages of contracted (frozen) shoulder: a home muscle function retraining programme or outpatient physiotherapy (with passive mobilisations) and standard home exercises?

**References:** Ginn and Cohen (2005).

**Settings:** Secondary care in Australia.

**Synthesis:** The quality of the evidence was low for patients’ global impression of change—‘improved’ or ‘not improved’—and adverse events. The 95% CI indicated that, in the population, the home muscle function retraining programme would result in from 321 fewer to 118 more ‘improved’ classifications per 1000 patients.

Potential harms of mechanical therapy include temporary aggravation of symptoms and would be common to both interventions. Adverse events were quantified but not described in the report of this trial. The relative risk was small, tending towards more adverse events in the muscle function retraining group (a difference of 3 patients per 1000); but the wide 95% CI meant that in the population, muscle function retraining might result in anywhere between 36 fewer and 600 more adverse events per 1000 patients.

**Summary of evidence:** The quality of the evidence is low and the estimates of effect relating to efficacy are imprecise. Adverse events would likely be minor, but there is potential for them to be much more numerous in patients treated with muscle function retraining.
**Recommendation:** Probably use outpatient physiotherapy (with passive mobilisations) and standard home exercises in preference to a home muscle function retraining programme for both stages of contracted (frozen) shoulder in secondary care.

3.1.3. In secondary care, which should we use for stiffness-predominant contracted (frozen) shoulder: high grade or low grade mobilisations?

**Settings:** Secondary care in The Netherlands.

**Synthesis:** The quality of the evidence varied by outcome, from very low (adverse events) to high (passive external rotation) and was moderate-to-low overall (mode).

In the short term, the 95% CIs for the SRQ (moderate quality evidence), night pain and pain on use (low quality evidence) crossed zero and the threshold for the MCID ion either side of zero. Thus it was unclear in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important. The 95% CI for passive external rotation, too, crossed zero (high quality evidence). The MCID for this outcome is not known, but the 95% CI was narrow (-3.5° to 6.3°) and of doubtful clinical importance.

In the medium and long term, the 95% CI for the SRQ again spanned zero, but indicated that the only potential for a clinically important effect in the population was in the direction of high grade mobilisations (moderate quality evidence). The same held for night pain and pain on use in the long term (moderate quality evidence). The 95% CI for passive external rotation spanned zero in the medium term, although it extended further in the direction favouring high grade mobilisations. In the long term, it favoured high grade mobilisations (high quality evidence). For the remaining medium and long term outcomes, the direction and clinical importance of effects in the population was not clear from the 95% CIs.

The evidence relating to adverse events was unusable because adverse events were pooled with the ‘no change’ category.

**Summary of evidence:** Overall, the evidence relating to efficacy is of moderate quality, while that relating to adverse events is very low (unusable). In the medium and long term, the only potential for a clinically important effect in SRQ favours high grade mobilisations. The 95% CIs for the pain outcomes fail to rule out clinically important effects in either direction in most instances. The 95% CIs for improvements in passive external rotation are directional in the medium and long term, favouring high grade mobilisations, although it is doubtful whether the effects would be clinically important. No data on adverse events are provided, though any such events would likely be temporary and minor. On this basis, the potential benefits are likely to outweigh the possible harms.

**Recommendation:** Probably use high grade mobilisations (in preference to low grade mobilisations) for stiffness-predominant contracted (frozen) shoulder in secondary care.
3.1.4. In secondary care, which should we add to home exercises for both stages of contracted (frozen) shoulder: high grade mobilisations or MWMs?

**References:** Yang et al (2007).

**Settings:** Secondary care in Taiwan.

**Synthesis:** The quality of the evidence was very low. The 95% CI for the FLEX-SF crossed zero and the threshold for MCID in either direction. Thus it is uncertain in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important.

Potential harms of mechanical therapy include temporary aggravation of symptoms and would be common to both interventions; but adverse events were neither quantified nor described in the report of this trial.

**Summary of evidence:** The quality of the evidence is low. It is uncertain in which direction (if any) change in the FLEX-SF would occur in the population, and whether any such change would be clinically important. Potential harms of mechanical therapy include temporary aggravation of symptoms. Adverse events would probably be minor and common to both interventions (although they were neither quantified nor described in the report of this trial); but uncertainty as to the interventions’ relative benefits means that no recommendation for practice can be made.

**Recommendation:** No recommendation.

3.1.5. In secondary care, should we add SWD to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder?

**References:** Leung and Cheing (2008).

**Settings:** Secondary care in Hong Kong.

**Synthesis:** The quality of the evidence was moderate. Most of the 95% CI for the patient-competed section of the ASES lay above the threshold for MCID favouring the addition SWD. Therefore a clinically important effect favouring the addition of SWD might tentatively be expected in the population.

Potential harms of SWD include burns, but there are well established protocols for minimising the risk of these occurring. Adverse events were neither quantified nor described in the report of this trial.

**Summary of evidence:** The quality of the evidence is moderate. The patient-competed section of the ASES is suggestive of a clinically important effect favouring SWD in the population. Potential harms of SWD include burns, but there are well established protocols for preventing these. (Adverse events were neither quantified nor described in the report of this trial.)

**Recommendation:** Probably add SWD to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder in secondary care.
3.1.6. In secondary care, should we add hot packs to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder?

**References:** Leung and Cheing (2008).

**Settings:** Secondary care in Hong Kong.

**Synthesis:** The quality of the evidence was low. The 95% CI for the patient-competed section of the ASES crossed zero and the threshold for MCID on either side. Therefore it is uncertain in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important.

Potential harms of hot packs include burns, but there are well established protocols for minimising the risk. Adverse events were neither quantified nor described in the report of this trial.

**Summary of evidence:** The quality of the evidence is low. It is uncertain in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important. Potential harms of SWD and hot packs include burns, but there are well established protocols for preventing these. (Adverse events were neither quantified nor described in the report of this trial.)

**Recommendation:** Probably don’t add hot packs to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder in secondary care.

3.1.7. In secondary care, which should we add to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder: SWD or hot packs?

**References:** Leung and Cheing (2008).

**Settings:** Secondary care in Hong Kong.

**Synthesis:** The quality of the evidence was moderate. The patient-competed section of the ASES showed a clinically important mean effect favouring the addition of SWD over hot packs. The 95% CI crossed zero, so the direction of effect in the population is uncertain, but the only potential for a clinically important effect was in the direction of SWD.

Potential harms of SWD and hot packs include burns, but there are well established protocols for minimising the risks. Adverse events were neither quantified nor described in the report of this trial.

**Summary of evidence:** The quality of the evidence was moderate. It is uncertain in which direction (if any) an effect would occur in the population, but the only potential for a clinically important effect favoured the addition of SWD. Potential harms of SWD and hot packs include burns, but there are well established protocols for preventing these. (Adverse events were neither quantified nor described in the report of this trial.)

**Recommendation:** Probably add SWD (in preference to hot packs) to outpatient physiotherapy (without passive mobilisations) and home exercises for stiffness-predominant contracted (frozen) shoulder in secondary care.
3.2. Physiotherapy versus other treatments

3.2.1. In primary care, which should we use for both stages of contracted (frozen) shoulder: outpatient physiotherapy (with mobilisations) or an intra-articular steroid injection?

Settings: Primary care in The Netherlands.

Synthesis: The overall (modal) quality of the evidence was moderate. The whole 95% CI for the short term SDQ lay above the threshold for MCID favouring steroid injection (high quality evidence). A clinically important effect favouring steroid injection may therefore be inferred to the population. The 95% CIs for the short term pain scores (day and night) were wide, both on the side of zero favouring steroid injection and both almost fully above the threshold for MCID (high quality evidence). An effect favouring steroid injection may therefore be inferred to the population, and a clinically important effect cautiously inferred.

In the medium term, the 95% CI for SDQ crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population; but the only potential for a clinically important difference was in the direction of steroid injection (moderate quality evidence). Other outcomes, at this time point and long term, were equivocal both in terms of direction of effects and their clinical importance.

Potential harms of physiotherapy include temporary aggravation of symptoms. Those of steroid injections include facial flushing, temporary aggravation of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were both quantified and described in the report of this trial (moderate quality evidence). Fifty-three percent of the injection group, and 56% of the physiotherapy group, reported adverse events. (Note that, in a deviation from protocol, 5 patients were treated with both interventions.) These adverse events were minor, and included: pain lasting a day or less after treatment (9 patients in the injection group; 17 patients in the physiotherapy group); pain lasting 2 days or more after treatment (16 patients in the injection group; 13 patients in the physiotherapy group); facial flushing (9 patients in the injection group; 1 patient in the physiotherapy group); irregular menstruation (2 patients in the injection group); self-diagnosed fever (2 patients in the injection group; 1 patient in the physiotherapy group); skin irritation (1 patient in the injection group; 2 patients in the physiotherapy group); and other events, including sweating, fatigue, dry mouth, dizziness and headache (6 patients in the injection group), and slight swelling, tingling and radiating pain (4 patients in the physiotherapy group). The 95% CI for relative risk indicated that between 43 and 535 fewer patients per 1000 would suffer adverse events with steroid injection than with physiotherapy.

Summary of evidence: The overall quality of the evidence is moderate. A clinically important effect favouring steroid injection may be inferred to the population in terms of SDQ, and cautiously inferred to the population in terms of VAS for day and night pain. In the medium term, it is uncertain in which direction (if any) an effect on SDQ would occur in the population, but the only potential for a clinically important difference is in the direction of steroid injection. Other efficacy
outcomes, at this time point and long term, are equivocal both in terms of direction of effects and their clinical importance. The adverse events reported were all minor. The 95% CI for relative risk indicates that between 43 and 535 fewer patients per 1000 would suffer adverse events with steroid injection than with physiotherapy. The possibility of longer term adverse effects of steroid injection (Shibata et al 2001) should be considered, however.

**Recommendation:** Probably use an intra-articular steroid injection rather than outpatient physiotherapy for both stages of contracted (frozen) shoulder in primary care.

3.2.2. In secondary care, which should we use for both stages of contracted (frozen) shoulder: a home muscle function retraining programme or a subacromial steroid injection?

**References:** Ginn and Cohen (2005).

**Settings:** Secondary care in Australia.

**Synthesis:** The quality of the evidence was low for patients’ global impression of change—‘improved’ or ‘not improved’—and adverse events. The 95% CI indicated that, in the population, the home muscle function retraining programme would result in 240 fewer to 255 more ‘improved’ patients per 1000.

Potential harms of mechanical therapy include temporary aggravation of symptoms. Those of steroid injection include facial flushing, temporary aggravation of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were quantified but not described in the report of this trial. The relative risk was small, tending towards more adverse events in the subacromial steroid injection group (a difference of 4 patients per 1000); but the 95% CI meant that in the population, subacromial steroid injection might result in somewhere between 43 fewer and 380 more adverse events per 1000 patients.

**Summary of evidence:** The quality of the evidence is low. The relative benefits and harms of the interventions are unclear.

**Recommendation:** No recommendation for practice.

3.2.3. In secondary care, which should we use for both stages of contracted (frozen) shoulder: out-patient physiotherapy (with passive mobilisations) and home exercises or a subacromial steroid injection?

**References:** Ginn and Cohen (2005).

**Settings:** Secondary care in Australia.

**Synthesis:** The quality of the evidence was low for patients’ global impression of change—‘improved’ or ‘not improved’—and adverse events. The 95% CI indicated that, in the population, outpatient physiotherapy and home exercises would result in 131 fewer to 348 more ‘improved’ patients per 1000.

Potential harms of mechanical therapy include temporary aggravation of symptoms. Those of steroid injection include facial flushing, temporary aggravation of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were quantified but not described in the report of this trial. The relative risk was small, tending towards more adverse events in the subacromial steroid injection group (a difference of 7 patients per 1000); but the 95% CI meant that
in the population, subacromial steroid injection might result in somewhere between 43 fewer and 535 more adverse events per 1000 patients.

**Summary of evidence:** The quality of the evidence is low. The relative benefits are unclear, but the results show less potential for benefit with subacromial steroid injection, and more potential for adverse events.

**Recommendation:** Probably use outpatient physiotherapy (with passive mobilisations) and home exercises in preference to subacromial steroid injection for both stages of contracted (frozen) shoulder in secondary care.

### 3.3. Physiotherapy versus combinations of physiotherapy and other treatments

3.3.1. In primary and secondary care, which should we add to home exercises for both stages of contracted (frozen) shoulder: outpatient physiotherapy (with passive mobilisations) or an intra-articular steroid injection?

**Settings:** Secondary care in Canada, primary care in Northern Ireland.

**Synthesis:** The overall (modal) quality of the evidence was moderate. From the 95% CIs for the short term combined pain–function outcomes, it could be inferred that an effect would favour the addition of steroid injection in the population: this 95% CI was almost completely above the threshold for MCID favouring steroid injection, so it could cautiously be inferred that the effect in the population would be clinically important (high quality evidence). The 95% CI for global pain crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population; but the only potential for a clinically important difference was in the direction of steroid injection (moderate quality evidence). The same pertained to the 95% CI for the combined pain–function outcomes in the medium term (moderate evidence). Other outcomes, at this time point and long term, and including passive external rotation, were equivocal both in terms of their directions of effects and their clinical importance.

Potential harms of mechanical therapy include temporary aggravation of symptoms. Those of steroid injection include facial flushing, temporary worsening of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were not quantified or described in either trial’s report.

**Summary of evidence:** The overall quality of the evidence is moderate. The estimates of relative benefits favour the addition of steroid injection (versus outpatient physiotherapy) to home exercises in the short term and potentially in the medium term. The estimates of relative benefits in the long term are too imprecise to enable a judgement. Adverse events were not mentioned in either trial report, but the results of another trial (van der Windt 1998) suggest that adverse events would be fewer in the steroid injection group. That trial did not investigate histology, however, and the possibility of adverse effects on collagen density should be borne in mind.

**Recommendation:** Probably add an intra-articular steroid injection (rather than outpatient...
physiotherapy with passive mobilisations) to home exercises for both stages of contracted (frozen) shoulder in primary or secondary care.
3.4. Adding physiotherapy to other treatments

3.4.1. In primary and secondary care, should we add outpatient physiotherapy (with passive mobilisations) and home exercises to distension for both stages of contracted (frozen) shoulder?

Settings: Primary and secondary care in Australia.
Synthesis: The overall (modal) quality of the evidence was moderate. The 95% CIs for the SPADI, global pain, pain at rest, at night and on use crossed zero and—where these were known—the thresholds for MCID on either side of zero, in the short and the medium term. Adverse events were more prevalent in the group that received distension and placebo physiotherapy.
Summary of evidence: The overall quality of the evidence is moderate. The estimates of relative benefits are too imprecise to enable a judgement. Adverse events were fewer in the physiotherapy and distension group than the placebo physiotherapy and distension group.
Recommendation: No recommendation for practice.

3.4.2. In primary and secondary care, should we add outpatient physiotherapy (with passive mobilisations) to NSAIDs for both stages of contracted (frozen) shoulder?

Synthesis: The quality of the evidence was moderate. The whole 95% CI for the SPADI lay above the threshold for MCID favouring the addition of physiotherapy. Therefore in the population, a clinically important effect favouring the addition of physiotherapy would be expected.

Potential harms of physiotherapy include temporary aggravation of symptoms; those of NSAIDs primarily gastro-intestinal (GI) disturbances. Adverse events were quantified and described in the report of this trial. Four patients reported pain lasting > 2 hours after physiotherapy. Fifteen patients in the NSAIDs group reported GI disturbances, and six of these had to stop medication due to severe dyspepsia. Two reported severe oedema (the site was unspecified) and one a severe headache which resoled on discontinuation of NSAIDs. The 95% for the relative risk indicated that the physiotherapy-related adverse events would be between 66 and 231 fewer per 1000 patients than those related to NSAIDs.

Summary of evidence: The quality of the evidence was moderate. The results point to a clinically important effect favouring the addition of outpatient physiotherapy (with passive mobilisations) in the population. The 95% CI for adverse events indicates that those attributable to NSAIDs would be between 66 and 231 more numerous per 1000 patients.
Recommendation: A combination of outpatient physiotherapy (with passive mobilisations) and NSAIDs is preferable to NSAIDs alone for both stages of contracted (frozen) shoulder in secondary care. (The potential harms of NSAIDs should be carefully considered, although such considerations fall outside the non-prescriber’s remit.)
3.5. Adding physiotherapy elements to combinations of physiotherapy and other treatments

3.5.1. In primary and secondary care, should we add outpatient physiotherapy (with passive mobilisations) to steroid injection and home exercises for both stages of contracted (frozen) shoulder?

**Settings:** Secondary care in Canada and primary care in Northern Ireland.

**Synthesis:** The overall (modal) quality of the evidence was moderate. The 95% CIs for the short term combined pain–function outcomes (high quality evidence) and global pain (moderate quality evidence) crossed zero, so the effect in the population could be in either direction; but the only potential for a clinically important effect favoured the addition of outpatient physiotherapy. The 95% CI for passive external rotation also crossed zero, but extended roughly the same distance on either side (high quality evidence): it is doubtful whether any change within this 95% CI would be clinically important.

In the medium term, the only potential for a clinically important effect on the combined pain–function outcomes favoured the addition of outpatient physiotherapy (very low quality evidence). However, the 95% CI for pain crossed zero and the threshold for MCID on either side, so it was unclear in which direction (if any) an effect would occur in the population, and whether any such effect would be clinically important (very low quality evidence). The 95% CI for passive external rotation also crossed zero. It extended further on the side favouring added physiotherapy, but with doubtful potential for clinical importance (high quality evidence).

The 95% CIs for the long term outcomes crossed zero and—where these were known—the thresholds for MCIDs on either side of zero. Therefore it was unclear in which directions (if any) effects would occur in the population, and whether such effects would be clinically important.

Potential harms of mechanical therapy include temporary aggravation of symptoms. Those of steroid injection include facial flushing, temporary worsening of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were not quantified or described in either trial’s report.

**Summary of evidence:** The overall quality of the evidence is moderate. The estimates of relative benefits favour the addition of steroid injection to outpatient physiotherapy and home exercises in the short term and potentially in the medium term. The estimates of relative benefits in the long term are too imprecise to enable a judgement. Adverse events were not mentioned in either trial report, but the results of another trial (van der Windt 1998) suggest that adverse events would be fewer in the steroid injection group. That trial did not investigate histology, however, and the possibility of adverse effects on collagen density should be borne in mind.

**Recommendation:** Probably add outpatient physiotherapy (with passive mobilisations) to an intra-articular steroid injection and home exercises for both stages of contracted (frozen) shoulder in primary or secondary care.
3.6. Adding other treatments to physiotherapy

3.6.1. In primary and secondary care, should we add an intra-articular steroid injection to outpatient physiotherapy (with passive mobilisations) and home exercises for both stages of contracted (frozen) shoulder?

Settings: Secondary care in Canada and primary care in Northern Ireland.

Synthesis: The overall (modal) quality of the evidence was moderate. From the 95% CIs for the short term combined pain–function outcomes and global pain (both high quality evidence), it could be inferred that a clinically important effect would favour the addition of steroid injection in the population. Passive external rotation demonstrated an effect in the same direction.

In the medium term, the 95% CI for the combined pain–function outcomes crossed zero, so it is uncertain in which direction (if any) an effect would occur in the population; but the only potential for a clinically important difference was in the direction of steroid injection (moderate quality evidence). Other outcomes, at this time point and long term, and including passive external rotation, were equivocal both in terms of their directions of effects and their clinical importance.

Potential harms of mechanical therapy include temporary aggravation of symptoms. Those of steroid injection include facial flushing, temporary worsening of symptoms and, possibly, diminished collagen density (Shibata et al 2001). Adverse events were not quantified or described in either trial’s report.

Summary of evidence: The overall quality of the evidence is moderate. The estimates of relative benefits favour the addition of steroid injection to outpatient physiotherapy and home exercises in the short term and potentially in the medium term. The estimates of relative benefits in the long term are too imprecise to enable a judgement. Adverse events were not mentioned in either trial report, but the results of another trial (van der Windt 1998) suggest that adverse events would be fewer in the steroid injection group. That trial did not investigate histology, however, and the possibility of adverse effects on collagen density should be borne in mind.

Recommendation: Probably add an intra-articular steroid injection to outpatient physiotherapy (with passive mobilisations) and home exercises for both stages of contracted (frozen) shoulder in primary or secondary care.
3.6.2. In secondary care, should we add MUA to home exercises for both stages of contracted (frozen) shoulder?

Settings: Secondary care in Finland.

Synthesis: The overall (modal) quality of the evidence was moderate. In the short term, the 95% CIs for the mean differences (as reported) of modified SDQ, the NPRS and passive external rotation crossed zero, so it was unclear in which direction (if any) effects would occur in the population. The MCID for the SDQ and passive external rotation was not known, but in the case of the NPRS, the only potential for a clinically important effect (this was marginal) was in the direction of home exercises only.

In the medium and long term, the 95% CIs for the mean differences (as reported) of all outcomes crossed zero, though at each time point the only potential for a clinically important effect on the NPRS in the population was in the direction of added MUA.

Potential harms of MUA include humeral fractures, rotator cuff ruptures, brachial plexus and vascular injuries; those of mechanical therapy include temporary aggravation of symptoms. Adverse events were neither quantified nor described in the report of this trial.

Summary of evidence: The overall quality of the evidence is moderate. The estimates of relative benefits show potential for added MUA to exert a clinically important beneficial effect over MUA alone on pain in the medium and long term. Adverse events were not reported but potential harms are recognised and may be serious. The balance of benefits and harms is unclear.

Recommendation: No recommendation for practice.

4. Recommendations for research

Approximately half (9/19) of our initially included trials were of low methodological quality and carried a moderate-to-high risk of bias. Of these, four were over 20 years old (Bulgen et al 1984, Dacre Beeney & Scott 1989; Lee et al 1973), but the remainder were published recently—between 2004 and 2008—postdating the CONSORT statement for reporting randomised trials (Altman et al 2001). It is disappointing that the CONSORT recommendations have yet to be generally implemented.

With respect to high quality trials, our survey of CSP members revealed a discrepancy between clinicians’ and researchers’ approaches. Clinicians differentiate between stages of contracted (frozen) shoulder and use this differentiation to guide their interventions, even though the stages have been inconsistently defined. We offered the terms ‘pain-predominant’ and ‘stiffness-predominant’ contracted (frozen) shoulder, for their clarity and non-ambiguity and, based on these terms, our respondents’ choice of clinical interventions was clearly dichotomised. This dichotomy—or indeed any staged classification—is not usually evident in the research literature. In a number of trials in which the stage of the condition appears to have been mixed, and in which interventions, comparators or both were physiotherapy, there was no explicit adaptation of treatment according to stage. These trials included Ginn and Cohen (2005), among whose physiotherapy treatments were a muscle function retraining programme and a package of outpatient physiotherapy with passive mobilisations and standard home exercises; Yang et al (2007), who studied high grade mobilisations and MWMs; and Pajareya et al (2004), whose trial included physiotherapy with passive mobilisations. With all three trials, it is unclear whether the failure to report adaptation of treatment by the condition’s stage represents an oversight or a true reflection of the method. In either case, the clinical applicability of these trials’ findings is somewhat compromised. It would be helpful if, in future, researchers in this area were to report their interventions and comparators in sufficient detail to remove ambiguity; and either to focus on a specific stage of contracted (frozen) shoulder (we suggest ‘pain-predominant’ or ‘stiffness-predominant’, with pain taking primacy in ambiguous cases), or to subgroup their results by the condition’s stage. The last two options might reveal therapeutic effects which are too dilute to detect in a generic sample.

We found a number of trials that used non-physiotherapy comparators in a way which does not mirror their application in practice. This applied particularly to steroid injection, whether intra-articular (Carette et al 2003, Ryans et al 2005, van der Windt et al 1998) or subacromial (Ginn & Cohen 2005), which was used as a comparator in studies of apparently mixed-stage contracted (frozen) shoulder. It would be interesting to know whether, as theoretical principles and clinical usage seem to suggest, such injections would be even more efficacious in studies (or subgroups) confined to the pain-predominant stage. If so, the relative efficacy of physiotherapy, against which the injections were compared, would be reduced.

For many comparisons, the estimates of effect were too imprecise to allow firm conclusions to be drawn: often, the direction of the effect was unclear, as was its clinical importance (see Results). For those comparisons considered worth pursuing, the studies require replication with sample sizes
sufficient to narrow the 95% CIs and facilitate more definitive conclusions. However, implementing this suggestion and some of those made above—i.e. focusing on specific stages of contracted (frozen) shoulder or sub-grouping—would require relatively large samples, and we recognise that recruitment to research is problematic. There is a strong case for multi-centre trials.

To a greater or lesser extent, the evidence for the efficacy of interventions may be specific to the care settings in which those interventions have been studied. Early on in the guideline development, we spent much time arguing about the relative merits of tests and treatments. We eventually realised the source of our disagreements: our group had been (deliberately) drawn from different care settings, and we were each accustomed to managing different populations. It is important to bear in mind that, while translating results from one care setting to another will often give useful guidance, there is an element of uncertainty inherent in the process. In our recommendations for practice we have taken care to clearly state the setting(s) from which the evidence was derived. Clearly, many questions remain as to the efficacy of interventions in different care settings.

Lastly, a number of physiotherapy modalities have not been specifically evaluated in relation to contracted (frozen) shoulder in any care setting. These include pulsed shortwave diathermy, TENS, interferential and ultrasound, although ultrasound has been studied in mixed shoulder pain populations, and consistently found ineffective (Ainsworth et al 2007 and review by Hanchard, Cummins & Jeffries 2004). Whether much is to be gained from evaluating the remainder in stand-alone fashion is very doubtful, but these interventions may have roles as part of therapeutic packages.

APPENDICES
APPENDIX A: Methods

i. Types of studies

We considered for inclusion RCTs and quasi-RCTs, both in the form of full reports only. Abstracts, ‘letters to the editor’, responses to such letters, commentaries and leaders were not considered.

ii. Types of participants

We intended to include in our review a reasonably homogeneous group of patients with contracted (frozen) shoulder. To this end we required in each trial report:

a. a statement that the sample—or a subgroup with separately reported outcomes—had been diagnosed with ‘adhesive capsulitis’, ‘capsulitis’, ‘contracted shoulder’, ‘frozen shoulder’ or an equivalent term (but not ‘periarthritis’8). No inclusion criteria were required in addition to this statement, but such criteria as were provided had to be consistent with a specific diagnosis of contracted (frozen) shoulder: thus inclusion of referred pain (from the neck), paraesthesia, painful arc, or pain or weakness on isometric actions was not acceptable.

Alternatively, we required:

b. that in relation to the sample—or a subgroup with separately reported outcomes—the report’s inclusion criteria:
   - should incorporate shoulder stiffness (ideally defining this as present on passive movement and affecting external rotation, with or without other movements); but
   - should not incorporate any features of non-capsular causes of shoulder pain (referred pain from the neck or paraesthesia, combined neck-shoulder pain, painful arc, or pain or weakness on isometric actions).

iii. Types of interventions

For the ‘standard physiotherapy’ section of the guidelines, we considered the following interventions:

- advice;
- exercise therapy;
- manual therapy;

8 ‘Periarthritis’ is an ambiguous term, considered by some to be synonymous with contracted (frozen) shoulder, but by others to include tendon and bursal disease (see Oxford Concise Colour Medical Dictionary). Therefore a diagnosis of ‘periarthritis’ was not an inclusion criterion per se.
• electrotherapy;
• heat or cold treatments; and
• ultrasound;

regardless of whether these have been used alone, in various combinations, or to supplement other interventions (e.g. corticosteroid injection, capsular distension, manipulation under anaesthetic).

iv. Types of comparisons

We considered comparison with any intervention or combination of interventions, with no intervention, or with placebo.

v. Types of outcome measures

Patients with frozen shoulder seek help for pain, functional difficulties or both. We therefore considered as our primary outcomes:

1. validated self-report instruments that included questions on shoulder pain and function (e.g. DASH, Oxford shoulder score); and
2. pain scores; whether at rest, at night or during activities; and whether stand-alone (e.g. 100 mm VAS, 11-point NPRS) or part of composite shoulder pain and function outcome instruments.

We also considered as primary outcomes:

3. passive or gravity-assisted range of passive external rotation, because restriction of this movement is thought to characterise the fact and severity of frozen shoulder more than any other single factor; and
4. adverse effects.

In the absence of 1, above, we considered the following secondary outcomes, in order of preference:

5. validated composite subjective/objective outcome measures (e.g. Constant Murley score);
6. other reportedly ‘primary’ subjective outcome measures (e.g. patients’ global impression of improvement); and
7. other reportedly ‘primary’ objective outcome measures (e.g. independent assessor’s global impression of improvement).
vi. Search methods for identification of studies

We designed our search strategy to cover all interventions that might be undertaken by a physiotherapist though, as detailed above, the guidelines will address these in stages, starting with ‘standard physiotherapy’ in this version (now version 1.1). Our first step was to identify in the Cochrane Library (http://www.cochrane.org/) the Cochrane reviews of interest. There were four: (1) Buchbinder, Green and Youd (2003) on corticosteroid injections for shoulder pain; (2) Buchbinder et al (2008) on arthrographic distension for adhesive capsulitis (frozen shoulder); (3) Green, Buchbinder and Hetrick (2003) on physiotherapy interventions for shoulder pain; and (4) Green, Buchbinder and Hetrick (2005) on acupuncture for shoulder pain.

We noted the trials included in these Cochrane reviews, obtained the original reports of these trials and, where necessary, filtered out those that were not applicable to the present guidelines. We then derived our search strategy from the Cochrane reviews, increasing its specificity to contracted (frozen) shoulder as indicated below (see Search strategy), and ran searches on the Ovid MEDLINE, AMED, CINAHL and EMBASE databases from 2001 to 09 July 2008, using the OvidSP platform. Thus our search period overlapped with that of the earliest of the four Cochrane reviews (Green, Buchbinder & Hetrick 2003), whose cut-off for inclusion of trials was June 2002.

Search strategy
(The numerals in superscript correspond to the Cochrane reviews listed above, and indicate the source of the search terms. Where the original terms were adapted, this is specified.) Note that truncation and wildcards were consistent across the OvidSP platform. For database-specific comments on the search strategy, see TABLE A1.1.

**TABLE A1.1. Database-specific comments on the search strategy**

After de-duplication, this strategy retrieved 749 citations, most with abstracts.

**Filtering**

Filtering was independently conducted by two reviewers, who resolved any disagreements by consensus.

**Preliminary filtering**

In a preliminary filtering process (based on titles and—where these were available—abstracts), we included citations which:

- reported one or more conservative interventions (within the extended scope of physiotherapy practice) for intrinsic, musculoskeletal-type shoulder pain unrelated to significant trauma, stroke, or systemic inflammatory conditions.
We excluded those which:

- excluded from consideration contracted (frozen) shoulder;
- focused on peri-operative and post-operative procedures except where these explicitly related to the management of contracted (frozen) shoulder e.g. MUA; or
- were included in any of the four Cochrane reviews underpinning our own.

Secondary filtering

Secondary filtering was based on titles, abstracts and the full text of reports, as required. We included reports on:

- RCTs and quasi-RCTs.

We excluded reports:

- in which contracted (frozen) shoulder could not be identified as a distinct subgroup;
- no separate analysis was provided for the contracted (frozen) shoulder subgroup;
- of trials still in progress;
- of trials not directly relevant to physiotherapy; or
- which duplicated other, included, reports.

vii. Data collection and analysis

Data extraction was conducted in accordance with an a priori protocol. Data for each included trial were extracted on standardised forms by two independent reviewers. The independent reviewers also evaluate the risk of bias, using the criteria from the PEDro scale (http://www.pedro.fhs.usyd.edu.au/). PEDro was designed for, and is validated for, RCTs of physiotherapy. It includes clear guidance. Moreover, since it was used in the 2003 Cochrane review on physiotherapy interventions (Green, Buchbinder & Hetrick 2003), we considered its use in our review sensible for reasons of consistency. However, Green, Buchbinder and Hetrick (2003) did not use the PEDro scale’s facility for numerically scoring methodological quality, and neither did we, since numerical methods scores have been criticised for their arbitrariness (Cochrane Handbook 2009).

Where it made sense to do so, we performed meta-analyses. We did not anticipate undertaking any sensitivity or subgroup analyses, and did not do so. We did anticipate that the included trials would use a range of outcome measures. For dichotomous outcomes (e.g. ‘improved’/‘not improved’) we calculated the Relative Risk (RR) and its 95% confidence interval (95% CI). For outcomes measured on continuous scales we calculated the Mean Difference (MD) and its 95% CI. To pool trials which measured the same outcome but with different tools, e.g. SPADI and SRQ, we calculated the Standardised Mean Difference (SMD) and its 95% CI. We then converted the SMD and its 95% CIs back into the units of one of the original outcomes, since these are more meaningful clinically than the SMD (Cochrane Handbook 2009). To further enhance clinical relevance, we reported the Minimal Clinically Important Difference (MCID), if known, for all outcomes. We derived within-subject MCIDs from the research literature, but multiplied these by
0.4. We applied this adjustment because between-groups MCID (i.e. an important difference between groups, as in a controlled trial) is thought to approximate to 40% of that within individuals (Finch et al 2002). These processes allowed us to see whether the outcome and its 95% CI (a) overlapped zero and (b) overlapped the adjusted threshold for MCID on either side of zero. If the 95% CI did not overlap zero it could be stated, with 95% confidence, that the intervention had a directional effect. Furthermore, a 95% CI that lay entirely beyond the adjusted threshold for a MCID could be said, with 95% confidence, to have a clinically important effect favouring that intervention.

If insufficient data were available to calculate these statistics, we reported the fact, but did not contact the authors for additional information.

viii. Questionnaire survey of CSP members

We conducted a survey of Chartered Society of Physiotherapy (CSP) members in order to:

- obtain a snapshot of physiotherapists’ approaches to diagnosis and treating contracted (frozen) shoulder at the present time, enabling us to:
  - identify the treatment options currently in use and focus on these in our overview of interventions (section 1.6);
  - set the overview of interventions in context;
  - establish a baseline against which the guidelines’ impact might be evaluated; and
- identify discrepancies between practice and research.

We posted notices on eight special interest networks of the interactive CSP (iCSP) website, to whose subscribers contracted (frozen) shoulder might be of interest. The notices invited subscribers to follow a link to self-administered, on-line questionnaire. The questionnaire required respondents to state whether or not they had a ‘special interest’ in contracted (frozen) shoulder, because we were interested to see whether this distinction affected the diagnostic and management strategies they used; and to differentiate according to whether pain or stiffness was the primary problem.
Grading the quality of evidence and strength of recommendations from supplementary systematic review of interventions

**GRADE system**

Finally, we graded the quality of the evidence and derived our recommendations using the GRADE system, which is recommended by the Cochrane Collaboration, transparent, and increasingly in standard use. Specifically, we graded the quality of the evidence using GRADEprofiler version 3.2.2 software, which was developed by the GRADE Working Group [http://www.gradeworkinggroup.org/index.htm](http://www.gradeworkinggroup.org/index.htm) and is available at [http://www.ims.cochrane.org/revman/gradepro/download](http://www.ims.cochrane.org/revman/gradepro/download). GRADEprofiler facilitates tabulation of the results for each outcome, and helps to make judgements on the quality of the available evidence transparent. Aspects of quality include:

- Design and limitations (risk of bias);
- inconsistency (which occurs when trials’ results do not agree);
- indirectness (which occurs when the trials’ results are inapplicable to the population of interest);
- imprecision (which occurs when the estimates of effect are wide); and
- publication bias (underestimation or overestimation of effects due to selective publication of trials).

The resulting tables—GRADE evidence profile tables—are in APPENDIX E.

Our recommendations for management took the quality of the evidence into account. When evidence is graded ‘high’, it means that further research is unlikely to change our confidence in the estimated effect; when it is ‘moderate’, further research is likely to influence our confidence in the estimated effect, and may change the estimate; when it is ‘low’, further research is very likely to seriously influence our confidence in the estimated effect, and is likely to change the estimate; and when it is ‘very low’, any estimate of effect is very uncertain. With the quality of the evidence taken into account, potential benefits were weighed against potential harms and, if feasible, a recommendation for management made. As recommended by the GRADE Working Group, we used four classifications of recommendation: ‘do it’, ‘probably do it’, ‘probably don’t do it’ and ‘don’t do it’. ‘Do it’ or ‘don’t do it’ indicate a judgement that most well informed people (i.e. patients) would make. “Probably do it” or “probably don’t do it” indicate a judgement that a majority of well informed people would make but a substantial minority would not’ (GRADE Working Group 2004).

‘A recommendation to use or withhold an intervention does not mean that all patients should be treated identically. Nor does it mean that clinicians should not involve clinicians in the decision, or explain the merits of the alternatives. However, because most well informed patients will make the same choice, the explanation of the merits of the alternatives may be relatively brief. A recommendation is intended to facilitate an appropriate decision for an individual patient or a population. It should therefore reflect what people would likely choose, based on the evidence and their own values or preferences in relation to the expected outcomes. A recommendation to “probably do something” indicates a need for
clinicians to more fully and carefully consider patients’ values and preferences when offering them the intervention.’ (GRADE Working Group 2004)

In instances where the evidence was insufficient to make a recommendation for practice, we reserved judgement.

We have not considered economic data in this iteration of the guidelines.

x. Ensuring ‘fitness for purpose’

To ensure the guidelines’ ‘fitness for purpose’ we engaged our diverse target audience to become expert panellists in the development process using Delphi methods. Our strategy was as follows.

- The core group wrote the framework of the guidelines.
- Each of the framework’s three sections was then populated by one subsection: a sample of its proposed content.
- The draft was distributed to the Delphi expert panel, so the panellists could express their views (up to six comments each) on the broad structure of the guidelines as well as more detailed aspects of their level and style of reporting.
- The comments were collated and redistributed to the panel, who were asked to indicate ‘agree’, ‘disagree’ or ‘no opinion’ in relation to each.
- We proceeded with the guidelines development as directed by the consensus of opinion (the majority).

In our opinion, engaging stakeholders in an early, formative role is an improvement on the norm in guidelines development.

<thead>
<tr>
<th>Trial</th>
<th>Buchbinder et al (2007)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Methods</strong></td>
<td>Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: YES; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.</td>
</tr>
<tr>
<td><strong>Population</strong></td>
<td>149 patients diagnosed with frozen shoulder: probably a mix of pain-predominant and stiffness-predominant. Inclusion criteria: age ≥ 18 years, symptoms of pain and stiffness in predominantly 1 shoulder for ≥ 3 months, and restriction of passive motion ≥ 30° in ≥ 2 planes of movement, measured to onset of pain with a gravity inclinometer. Exclusion criteria: pain ≥ 7/10 on VAS at rest; systemic inflammatory joint disease; radiologic evidence of shoulder osteoarthritis, fracture, or calcification; reason to suspect a complete rotator cuff tear (arm elevation weakness, positive drop arm sign, high-riding humerus on shoulder radiograph, or complete rotator cuff tear on ultrasound); contraindications to arthrogram and/or distension such as current warfarin therapy; allergy to local anesthetic or iodinated contrast; pregnancy; likely not to attend for treatment or comply with follow up; inability to partake in moderate exercise; previous post-distension physiotherapy; and lack of written informed consent. Mean age ± SD, % female: Physiotherapy group 55 ± 9 years, 68%; Placebo group 55 ± 8 years, 58%. Setting Recruitment was from primary care and ‘specialized practice’ [secondary or tertiary care]. Trial took place in Victoria, Australia.</td>
</tr>
<tr>
<td><strong>Intervention/Comparison(s)</strong></td>
<td>Arthrographic joint distension + physiotherapy versus arthrographic joint distension + placebo physiotherapy. Arthrographic distension of the glenohumeral joint with corticosteroid and normal saline was done under radiologic guidance at one of several community-based radiology practices. Patients received physiotherapy or sham physiotherapy from experienced physiotherapists, twice weekly for 2 weeks then once weekly for 4 weeks (8 visits, 30 minutes each). The physiotherapist-patient interaction was standardised. Physiotherapy: The goals were to maintain and increase active and passive glenohumeral range by stretching soft tissue structures adjacent to the joint; to improve strength, particularly within newly gained passive range; and to regain proprioception and normal shoulder and trunk biomechanics. Specific interventions included: passive and self-executed muscle stretching techniques to stretch muscles passing over the glenohumeral joint, cervical and thoracic spine mobilisation, glenohumeral joint passive accessory glides, glenohumeral joint passive physiologic mobilisation including rotation, strength and coordination exercises for rotator cuff and scapular stabilisers, and proprioceptive challenge. At the end of the 6-week program, patients were instructed to maintain their 10-minute daily home exercise program, recording these sessions in a logbook. Placebo physiotherapy: Patients underwent 8 sessions of sham ultrasound and application of a non-therapeutic gel. They received no instruction in exercise techniques and no manual therapy. This protocol had been used previously with successful blinding demonstrated in 81% of placebo-treated participants.</td>
</tr>
<tr>
<td>Accepted outcome(s)</td>
<td>SPADI (a self-administered tool scored out of 100, with higher scores indicating greater pain or disability). Overall assessment of pain, pain at night, activity-related pain and pain at rest on a 10-point Likert scale. Adverse events by open-ended questions. Timing of assessments: (1) Baseline; (2) End-point: 6 weeks; (3) Follow-up: 12 and 26 weeks.</td>
</tr>
</tbody>
</table>
More patients in the placebo group had post-operative capsulitis than those in the active group: 17 (23%) versus 9 (12%).

Trial: Bulgen et al (1984)*

Methods:
- Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: NO; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: NO.

Population:
- 42 patients explicitly diagnosed with ‘frozen shoulder’ and apparently at the pain-predominant stage, since the inclusion criteria stipulate, in addition to restricted active and passive movement in all ranges (including > 50% restriction of external rotation), that participants be unable to lie on the affected side. Mean age (range), % female: 59 (44-74) years, 67%. Setting: Secondary or tertiary care. Trial took place in a Rheumatology Research Centre in a UK hospital.

Intervention/Comparison(s):
- Mobilisation versus ice versus steroid injection versus no treatment. The mobilisation group received Maitland's mobilisations from a research physiotherapist 3 times weekly for 6 weeks. The steroid injection group received 20 mg methyl prednisolone acetate 20 mg and 0.5 ml 1% lignocaine hydrochloride injected into the subacromial bursa, and a similar amount into the shoulder joint by the anterior route, weekly, for three weeks. The ice group had ice packs followed by proprioceptive neuromuscular facilitation (PNF) supervised by the same research physiotherapist. All patients were taught pendular exercises and advised to do them for 2-3 minutes every hour. Non-salicylate analgesics and diazepam 5 mg at night were available as required.

Accepted outcome(s):
- Pain at rest, pain on movement and night pain were initially recorded on a 10 cm VAS and by verbal reports: ‘better’, ‘same’, or ‘worse’ (adverse events). The VAS was later abandoned but the verbal reports retained. Passive ranges of movement were also measured. Timing of assessments: (1) Baseline, (2) In-trial and end-point: weekly for 6 weeks (3) Follow-up: monthly for a further 6 months.

Period of data collection:
- Unspecified

Notes:
- Data presentation incompatible with meta-analysis or tabulation, but trial included in review by Green, Buchbinder and Hetrick (2003) and the present review for narrative purposes. (Bulgen et al. concluded that there was ‘little long term advantage in any of [their] treatment regimens over no treatment, but that steroid injections may benefit pain and range of movement in the early stages [though not statistically significantly so]. There [appeared] to be little place for physiotherapy alone, and, if used, it should not be continued for more than four weeks’.)

Methods:
- Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: NO; Intention-to-treat: YES; point measures and measures of variability: YES.

Population:
- 95 shoulders diagnosed with adhesive capsulitis in 90 patients. Inclusion criteria: > 1 month’s pain; limited active and passive shoulder movement, with decreased range of passive movement of > 20% in ≥ 3 ranges; negative Neer’s test. Exclusion criteria: Previous injection of involved shoulder; Allergy to local anaesthetics, steroids or sodium hyaluronate; coagulation disorders; cervical radiculopathy, fracture dislocation or rotator cuff tears; haematological, infectious, neurological, endocrine, cardiovascular, hepatic, renal or malignant disease; severe osteoporosis. Mean age ± SD, % female: Group 1 60 ± 10 years,
Comparison(s) | Intervention/Comparison(s) | Notes
---|---|---
 | Group 1: 30 mg sodium hyaluronate (Orthovisc) was injected into the shoulder joint using a posterior approach, weekly for 2 weeks. Group 2: 40 mg triamcinolone acetonide (Kenakort-A) was injected into the shoulder joint using a posterior approach. Group 3: Physiotherapy comprised a 20-minute hot pack, ultrasound at 1.5 W/cm² for 5 minutes, transcutaneous electrical nerve stimulation at the patient’s tolerance for 20 minutes and stretching exercises daily for 10 days. No other details were given. Group 4: All patients, including control patients, were advised on a home exercise programme including stretching and Codman (pendular) exercises, and the use of paracetamol if necessary. | There were 3 patients with bilateral involvement in Group 1, and 1 in each of Groups 2 and 3.

Accepted outcome(s) | Pain severity, measured on a 10 cm VAS; passive external rotation; Constant score. Adverse events in individuals were not specified as outcomes. | Timing of assessments: (1) Baseline; (2) In – trial and end-point: None; (3) Follow-up: 15 days, 3 months.

Period of data collection | Unspecified | |

Notes | | |

Methods | Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: NO*; Blinding of subjects: YES†; Blinding of therapists: YES†; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES. *Gender was not evenly distributed between the groups, so analyses were adjusted for this. †In the injection groups. ‡Primary outcome measure, but not secondary outcomes, analysed by intention-to-treat. | |

Participants | 93 patients aged $\geq 18$ and symptomatic $< 1$ year with adhesive capsulitis. Pain-predominant and stiffness-predominant stages were included (but managed differently from the physiotherapy perspective – see below). Inclusion criteria: Shoulder pain with limitation of both active and passive movements of the glenohumeral joint of $> 25\%$ in at least 2 directions versus the contralateral shoulder or normal values (reference supplied). Patients were required to have a total score $> 30$ on Shoulder Pain And Disability Index (SPADI). Exclusion criteria: Capsulitis secondary to another cause including inflammatory, degenerative, metabolic or infectious arthritis, CVA or fracture; known blood coagulation disorder or allergy to radiologic contrast material. From March 1997, recruitment difficulties led to the acceptance of patients with diabetes mellitus. Mean age $\pm SD$, % female: Group 1 55 $\pm$ 10 years, 65%; Group 2 57 $\pm$ 9 years, 61%, Group 3 55 $\pm$ 11 years, 67%; Group 4 54 $\pm$ 8 years, 46%. Setting: Secondary care. Trial took place in outpatient rheumatology clinics in 7 centres across Quebec and Ontario, Canada. | Before randomisation, the physiotherapists responsible for baseline and follow up assessments taught all patients a 10-minute home exercise programme to be done twice daily for 3 months. This included active and auto-assisted exercises in all ranges. Advice about intensity, frequency, progression of the exercises, heat and ice applications, and suitable shoulder positions was also given. Compliance was diarised during the first 3 months of the trial. Injections were done under fluoroscopic guidance by trained radiologists on the day of randomisation and comprised, in Group 1, 40 mg triamcinolone hexacetonide (2 ml) or, in Group 2, isotonic saline (2 ml). The syringes were prepared by the hospital pharmacist and covered in foil so that neither the injector nor the patient knew what substance was injected. Patients randomised to Groups 3 and 4 received injection + physiotherapy, starting their physiotherapy programme 1 week after injection (of triamcinolone or saline). This...
comprised 3 x 1-hour sessions given each week for 4 weeks (12 sessions). Physiotherapy differed according to whether the capsulitis was 'acute' (meeting ≥ of the following criteria) or 'chronic': (1) pain at rest ≥ 4 cm on a 10 cm VAS; (2) pain at rest present ≥ 75% of the day; (3) pain on active shoulder elevation ≥ 4 cm on a 10 cm VAS; (4) night pain; (5) spasm or 'empty' end-feel in at least 2 directions of passive motion. Patients with acute adhesive capsulitis received TENS followed by mobilisation techniques, active ROM exercises and ice application. Those with chronic adhesive capsulitis received ultrasound (to heat the deep joint structures) prior to mobilisation techniques, active and auto-assisted ROM techniques, isometric strengthening exercises and ice application. The 14 physiotherapists who took part in the trial (2 per centre) were each experienced in shoulder conditions and mobilisation techniques and each attended a 1-day training session before the trial for standardisation. Patients and their GPs were asked to limit concurrent interventions: all medications other than acetaminophen were stopped. A supply of the latter was given to patients with a form to record their use. Information on acetaminophen or other medication use was obtained at each follow-up.

Accepted outcomes

**Shoulder Pain And Disability Index (SPADI)** with decrease in total score ≥ 10 indicating clinically significant improvement in shoulder pain and function; and an increase > 10 indicating worsening of shoulder pain and function (reference given). **Passive external rotation** measured with a hydrogoniometer. Usually, each patient was measured by the same physiotherapist, blind to treatment allocation, through the trial. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline: SPADI and passive external rotation (2) End-point: SPADI at 6 weeks (primary outcome) and passive external rotation at 6 weeks (secondary outcome); (3) Follow-up: SPADI and passive external rotation at 3, 6 and 12 months (secondary outcomes).

Period of data collection

November 1996 – June 2000

Notes

Trial Cheing, So and Chao (2008)

Methods

Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: YES.

Participants

70 patients diagnosed with idiopathic frozen shoulder by an orthopaedic surgeon. The stage appears to have been pain-predominant since the Inclusion criteria state night pain, in addition to localised pain over one shoulder and restricted active and passive shoulder ROM. **Exclusion criteria:** History of trauma; fractures; history of shoulder surgery; cervical or thoracic pain syndrome; complex regional pain syndrome; malignancy; anticoagulant therapy; or acupuncture to the affected shoulder in the past 6 months. **Age range, % female:** 33–90 years, 83%. **Setting:** Secondary or tertiary care. Trial took place in Hong Kong.

Intervention/Comparison(s)

**Electro-acupuncture:** Patients received 10 sessions (2-3 times weekly) from the same physiotherapist (accredited to practice acupuncture) over a 4-week period. Following skin sterilisation with an isopropyl skin wipe, sterile, stainless steel acupuncture needles (0.30 x 40 mm) were inserted 15-25 mm intramuscularly into 3 acupoints including one trigger point, one local point (LI 15: Jianyu) and one distal point (ST38: Tiaokou). Trigger points were identified by areas of greatest tenderness around the painful shoulder. Needles were stimulated manually until the patient felt a needling response (de qi) locally. The two needles in the shoulder region were connected to an EA device and stimulated with an alternating frequency of 2-100 Hz at a pulse duration of 100-400 microseconds for 20 minutes. The intensity was adjusted to just below the threshold of pain. The distal needle was retained for 20 minutes and manually lifted and thrusted every 10 minutes. At the first session patients
were taught a home exercise programme. This involved following a chart and performing a standard set of shoulder mobilising exercises 5 times daily. The exercises comprised active assisted: flexion (using an overhead pulley), external rotation (using a cane), horizontal adduction (posterior capsular stretch) and internal rotation (using a towel). Each patient was given an exercise registration card to monitor compliance and asked to continue the exercise programme until the 6-month review. **Interferential electrotherapy (IFE).** These patients received 10 sessions of IFE over 4 weeks. A Phyaction Guidance E Unit was used to deliver current sweeping from 80-120 Hz via 4 suction electrodes in a co-planar arrangement around the shoulder region. The intensity was adjusted to just below pain threshold and the duration was 20 minutes. The patients were instructed to perform 'the same set of home exercise programmes' as those in the EA group, and an exercise registration care was also given to each subject. **Control.** These patients received no treatment for 4 weeks, but were invited to attend the assessment sessions at baseline and at the end of the fourth week. Afterwards, they received regular physiotherapy from other physiotherapists: no further data were extracted from them.

**Trial** | Dacre, Beeney and Scott (1989)* |
| Methods | Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: NO. |
| Population | 62 patients with ‘painful stiff shoulder’ apparently at the pain-predominant stage, since the **Inclusion criteria** state painful stiff shoulder for > 4 weeks, and pain at night causing sleep disturbance and inability to lie on the affected side, in addition to inability to use the affected arm with restriction of movement and loss of full function. **Exclusion criteria:** predisposing causes such as stroke, generalised arthritis, or cervical spondylosis; or highly localised lesions, such as bicipital tendinitis. **Mean age, % female:** 60 years, 55%. **Setting:** Secondary or tertiary care. Trial took place in London, England. |
| Intervention/ Comparison(s) | Physiotherapy alone versus steroid injection alone versus a combination of the two. Physiotherapy was performed for 4-6 weeks by one therapist who was free to choose the method, though mobilisation was the mainstay. Steroid injections comprised 20 mg triamcinolone ‘injected anteriorly around the shoulder joint’ by one physician. |
| Accepted outcome(s) | Pain assessed on a 10 cm visual analogue scale, with separate scores for day pain, night pain, and pain during active and passive movement. Passive movement of both affected and unaffected shoulders measured with a goniometer included glenohumeral external rotation. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) End-point: 6 weeks; (3) Follow-up: 26 weeks. |
| Period of data collection | Unspecified |
| Notes | Only illustrative examples of results were given, in graphic form, and it was not possible to accurately impute quantitative values to these. This data presentation was incompatible with meta-analysis or tabulation but trial included in review by Green, Buchbinder and Hetrick. |
The present review for narrative purposes. The authors concluded: ‘No treatment showed any advantage which was clinically relevant and significant at the 5% level.’

### Trial Ginn and Cohen (2005)

#### Methods
- Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: YES.

#### Population
- 138 volunteers with shoulder pain, of whom 77 had decreased abduction and/or flexion.
  - **Inclusion criteria:** Unilateral pain over the shoulder and/or upper arm > 1 month’s duration and aggravated by active shoulder movements; able to understand spoken English.
  - **Exclusion criteria:** Bilateral shoulder pain; shoulder instability; shoulder pain due to inflammatory or destructive disease or trauma in the preceding 4 weeks; referred pain from the spine. **Mean age and range and % female (for whole sample):** 55 years (22-90), 41%. **Setting:** Secondary care. Trial took place in a metropolitan public hospital in Sydney, Australia.

#### Intervention/Comparison(s)
- **Multiple treatment modalities (MTM):** Patients attended twice weekly for treatment, specifics of which were at the discretion of their treating physiotherapist (n = 6).
- Electrotherapy options were interferential, ultrasound, hot packs and ice packs. Passive mobilisation of the shoulder, sternoclavicular and acromioclavicular joints were also permissible. Range-of-motion exercises, which could be conducted with or without equipment, and which were not required by the protocol to be pain free, focused on abduction, flexion, extension, horizontal flexion and hand-behind back, all with excessive scapular movement discouraged. Exercises were progressed from active-assisted through active to resisted. Patients were also instructed in a daily home exercise programme. **Steroid injection:** A single injection of 40 mg methylprednisolone acetate and lidocaine was given subacromially. Afterwards, the patient was asked to use the shoulder normally. **Target exercise treatment:** This was a daily home routine aimed at restoring normal muscle function and hence dynamic stability and muscle co-ordination. It involved stretching shortened muscles, strengthening weakened muscles, improving co-ordination between muscles, and retraining scapulohumeral rhythm. Exercises were required to be pain free. Specific exercises in each case were chosen by the treating physiotherapist (n = 2), who reviewed the patient weekly for monitoring and progression.

#### Accepted outcome(s)
- The only outcome reported for the painful stiffness subgroup was perceived change: ‘improved’, ‘stable’ or ‘deteriorated’. This therefore included adverse events. **Timing of assessments:** (1) Baseline; (2) End-point: 5 weeks; (3) Follow-up: None.

#### Period of data collection
- 46-month period: dates unspecified.

### Notes

#### Trial Guler-Uysal and Kozanoglu (2004)

#### Methods
- Eligibility criteria specified: YES; Random allocation: NO; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: YES.

#### Population
- 40 patients (28 female; age range 43-82 years, mean 56 ± 8.6 years) diagnosed with shoulder
capsulitis, probably a mix of pain-predominant and stiffness-predominant. **Inclusion criteria:** Shoulder pain > 2 months with no major shoulder trauma, marked loss of active and passive shoulder motion, VAS score > 30 mm, normal AP and axillary lateral radiographs of the shoulder joint. **Exclusion criteria:** Polyarthritis, neurological disease or cervical neuropathy, medical conditions such as cardiac disease, infections, coagulation disorders, adhesive capsulitis secondary to shoulder dislocation, fracture, reflex sympathetic dystrophy or rotator cuff tears. **Mean age ± SD, % female:** 56 ± 9 years, 70%. **Setting:** Secondary or tertiary care. Trial took place in a physical medicine department in Adana, Turkey.

### Intervention/Comparison(s)

2 groups of 21 each. The **Cyriax group** received 3, 1-hour sessions weekly, comprising ‘deep friction massage and manipulation’ performed by the same experienced physical therapist. The **physical therapy group** were invited to the hospital every weekday for a 1-hour session comprising hot packs wrapped in towelling (20 minutes) and continuous SWD (20 minutes). **Both groups** performed active stretching and pendular exercises after each session, and were instructed in a standardised home exercise programme comprising passive ROM and pendular exercises to be performed daily. Use of NSAIDs or analgesic was not permitted throughout the trial.

### Accepted outcome(s)

Physical assessment was repeated by the same blinded observer. ROM was measured using a long-arm goniometer, and the patient supine, after every session. (It is unclear who performed these measurements). Treatments were stopped when 80% of normal range was attained. Attainment of 80% of normal range was therefore the trial’s primary outcome. Normal range was taken as 180° for flexion and abduction, 70° for medial- and 90° for lateral rotation (rotations being measured in 90° of shoulder abduction); so that minimum ranges of 150°, 150°, 55° and 70°, respectively, were required for a patient to be considered ‘recovered’. Other accepted outcomes are spontaneous pain, pain on motion, and night pain on a 100 mm VAS, and passive range of external rotation (measured at 90° of abduction with a long-armed goniometer). Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline, (2) In-trial and end-point: 1 and 2 weeks; (3) Follow-up: None.

### Period of data collection

Unspecified

### Notes

This is a perplexing study, because deep transverse friction, while originated by Cyriax, was not applied by him to contracted (frozen) shoulder. Details of the technique, not provided in the report, are therefore not available in the source cited. Moreover the term ‘manipulation’ is undefined.

### Study

Johnson et al (2007)

### Methods

Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: NO; Intention-to-treat: NO; point measures and measures of variability: YES.

### Population

18 patients diagnosed with adhesive capsulitis or frozen shoulder by any of 4 orthopaedic surgeons and referred for outpatient physiotherapy. Probably a mix of pain-predominant and stiffness predominant. **Inclusion criteria:** External rotation restriction that worsened with shoulder abduction, idiopathic or primary adhesive capsulitis (i.e. insidious onset with no history of major trauma but not excluding minor injuries), unilateral, age 25–80 years, normal x-ray within the previous 12 months. **Exclusion criteria:** External rotation restriction that lessened with shoulder abduction, previous shoulder surgeries to the affected shoulder, previous manipulations under anesthesia of the affected shoulder, shoulder girdle motor control deficits associated with neurological disorders (eg, stroke, or Parkinson’s disease). **Mean age ± SD, % female:** Anterior mobilisation group 55 ± 8 years, 80%; Posterior mobilisation group 50 ± 7 years, 75%. **Setting:** Secondary or tertiary care. Study took place in
**Intervention/Comparison(s)**

**Anterior mobilisation group:** 6 therapy sessions (2–3 per week) comprising therapeutic ultrasound to the anterior capsule (typically 3 MHz at 1.5 W/cm² continuous for 10 minutes, intended to heat the capsule) then anterior mobilisations. During lateral traction, Kaltenborn grade III mobilisations were performed at the end-range of available combined abduction and external rotation, with non-oscillatory stretches of ≥1 minute. Each session included a total of 15 minutes’ sustained stretch. This was followed by upper body ergometer exercise in pain-free flexion range to reduce post-mobilisation soreness. **Posterior mobilisation group:** as above except that ultrasound (1 MHz) was applied to the posterior capsule, (1 MHz), the mobilisation was posterior, and the starting position was progressed to maximum flexion and external rotation. **Both groups:** Handout instructions were given on pain free activities of daily living on entering the study.

**Accepted outcome(s)**

5 items of the 21-item self-assessment function questionnaire developed by L’Insalata et al (full reference given). Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) End-point: 2 or 3 weeks; (3) Follow-up: None.

**Period of data collection**

October 2003 – January 2005

**Notes**

Study

Khan et al (2005)

Methods

Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: NO; Intention-to-treat: NO; point measures and measures of variability: NO.

Population

35 patients attending out-patients of the Departments of Physical Medicine or Department of Radiology of a tertiary referral medical college. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder, thus: **Inclusion criteria:** Age 13–69 years, shoulder pain > 1 month, restricted movement. **Exclusion criteria:** Lack of consent, trauma to or around the shoulder in the past 2 months, pain and restriction of the shoulder secondary to identified causes (e.g. hemiplegia, cervical radiculopathy, IHD, rheumatological syndromes, infective conditions, reflex sympathetic dystrophy, part of a systemic illness), pregnancy and lactation. Mean age ± SD, % female: **Arthrography group** 50 ± 17 years, 50%; **Physiotherapy-only group** 50 ± 10 years, 35%. **Setting:** Tertiary care. Study conducted in Bangladesh, India.

**Intervention/Comparison(s)**

**Arthrography group:** A posterior approach was made using a 24 G needle: 2 cc xlocaine, 10 cc 75% urovideo and 1 cc (40 mg) depot medrol, drawn together in normal saline were injected under fluoroscopic guidance. **All patients received physiotherapy:** comprising therapeutic exercises (hold-relax, rotator cuff, pulley, pendular and wall-climbing exercises), TENS 3 days a week and infra-red 3 days a week. Length of course of physiotherapy is unspecified.

**Accepted outcome(s)**

Pain scored on a 0–100 VAS. Adverse events: exacerbations in pain reported on an individual basis. **Timing of assessments:** (1) Baseline; (2) In-trial: Every visit; (3) Follow-up: 8 weeks.

**Period of data collection**

December 1996–November 1997

**Notes**

Study

Kivimäki et al (2007)

Methods

Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of
**Population**

125 patients with stiff, painful shoulders recruited from 3 regional hospitals. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder. **Inclusion criteria:** Adult patients with gradually increasing shoulder pain and stiffness screened on the basis of x-ray and physical examination by physical medicine and rehabilitation specialists; < 140° elevation and < 30° passive external rotation. **Exclusion criteria:** arthritis, traumatic bone or tendon changes. Suspected cuff tears were ultrasound scanned and, if confirmed, excluded. **Mean age ± SD, % female:** Manupulation group 53 ± 8 years, 71%; Control group 53 ± 9 years, 65%. **Setting:** Secondary or tertiary care. Study took place in Southern Finland.

**Intervention/Comparison(s)**

The manipulation group underwent manipulation under anaesthetic within 2 weeks of randomisation. With the patient supine, the physician elevated the humerus into scaption while supporting the scapula against the patient’s thoracic cage. In the elevated position, the humerus was gently rotated internally and externally. Any cracking sound was recorded. Normal or near-normal mobility was attained during these procedures. The manipulation and control groups received physiotherapy advice in 2 sessions and written instructions for a daily training, which included pendular exercises and stretching techniques for the shoulder joint.

**Accepted outcome(s)**

Modified Shoulder Disability Questionnaire (with 2 questions omitted from the standard 16-point questionnaire), pain intensity on an 11-point scale, passive external rotation using a universal goniometer. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) End-point: None; (3) Follow-up: 3, 6 and 12 months.

**Period of data collection**

June 1999–September 2002

**Notes**

Study

Lee et al (1973)*

Methods

Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: NO; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: NO.

Population

80 outpatients (gender unspecified) with ‘periarthritis’ of the shoulder, defined as pain with limitation of passive movement. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder. **Age and % female:** not stated in original article, but mean age reported as 58 years by Green, Buchbinder and Hetrick (2000), presumably following correspondence with authors. **Setting:** Secondary or tertiary care. Study took place in Leeds, England.

**Intervention/Comparison(s)**

4 groups of 20 each. **Group 1** received a course of infrared and graduated active exercises according to tolerance. **Group 2** received an intra-articular injection of 25 mg hydrocortisone acetate via the anterior approach below the coracoid process, followed by the same graduated exercises. **Group 3** received an injection of 25 mg hydrocortisone acetate into the biceps tendon sheath, followed by the same graduated exercises. **Group 4** was a control and received only analgesia.

**Accepted outcome(s)**

Movements measured were active lateral and medial rotation with the arm by the side and active and passive abduction; but a single outcome was generated from these components. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) In-trial and end-point: weekly for 6 weeks (for groups 1-3) and 6 weeks (for group 4); (3) Follow-up: None.
Period of data collection | Unspecified
---|---
Notes | Group averages (means?) were presented graphically without error bars. There was no statistical analysis. This data presentation was incompatible with meta-analysis or tabulation but the trial was included in the review by Green, Buchbinder and Hetrick (2008) and the present review for narrative purposes. (The active intervention groups all fared better than the control at every time point; among these groups, that receiving intra-articular injection plus exercises fared best. Injection of the biceps tendon sheath conferred no benefit over heat and exercises alone: in both of these groups benefits reached a plateau at week 3.)

Study | Leung and Cheing (2008)
---|---
Methods | Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

Population | 30 patients suffering from ‘stiffness phase’ [stiffness-predominant] idiopathic frozen shoulder as diagnosed by an orthopaedic surgeon. **Inclusion criteria:** Shoulder pain and limited movement for at least 8 weeks. **Exclusion criteria:** History of trauma to the shoulder, acute signs of inflammation over the shoulder, intrinsic shoulder pathology, taking analgesic or anti-inflammatory drugs, metal implants, impaired sensation of hot and cold, pregnancy or a cardiac pacemaker. **Mean age ± SD, % female:** 60 ± 13 years, 70%. **Setting:** Secondary or tertiary care. Study took place in Hong Kong.

Intervention/Comparison(s) | **Shortwave diathermy (SWD).** SWD was applied by the through-and-through method, with subjects seated. Intensity was adjusted until comfortable warmth was perceived, and this perception was maintained by further adjustments throughout the treatment if necessary. 20 minutes treatment was given 3 times a week for 4 weeks. **Hot pack.** An electrical 35.5 x 68.5 hot pack was used, with its temperature set at 63º C. Patients were instructed that only comfortable warmth should be perceived, and the temperature was adjusted as necessary to maintain this perception throughout the treatment. 20 minutes treatment was given 3 times a week for 4 weeks. Immediately after either heat treatment, patients were asked to perform 4 **stretching exercises** in a fixed sequence: external rotation; flexion; hand behind the back; and horizontal adduction (posterior capsular stretch). Each stretch was sustained for 30 sec, followed by 10 sec rest, and repeated 4 times. Patients were asked to repeat the stretches at home every day. A therapist checked for compliance with the exercise regime. In the **stretching exercises only** group, the procedure was identical.

Accepted outcome(s) | Measures included the American Shoulder and Elbow Surgeons Assessment form (ASES). This has a patient self-completed section designed to measure pain and functional limitation, (reference given). A further section of the ASES was physician-completed, and involved measurement of ROM. Data for external rotation were separately reported, but unclear was whether this was passive or active range. All assessments were performed by the same physiotherapist who was blinded to subject and intervention order throughout. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) In-trial and end-point: Week 2 and 4; (3) Follow-up: Week 8.

Period of data collection | Unspecified
---|---
Notes |
### Study: Nicholson (1985)*

**Methods**
- Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: NO; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: NO; point measures and measures of variability: YES.

**Population**
- 20 patients explicitly diagnosed with ‘adhesive capsulitis’ as indicated by the presence of shoulder pain and limited passive movement at the glenohumeral joint. Probably a mix of pain-predominant and stiffness-predominant stages. **Mean age (range), % female:** 53 (20–77 years), 50%. **Setting:** Care setting unclear. Study took place in Alabama, USA.

**Intervention/Comparison(s)**
- A 4-week course of *mobilisation plus active exercises versus active exercises alone*. Choice of mobilisation techniques was based on assessment of accessory movements on a patient-by-patient basis.

**Accepted outcome(s)**
- Measurements included: completion of a pain questionnaire, of which no further details are given; active internal and external rotation and abduction; and passive abduction. Adverse events were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) In-trial and end-point: Weekly for 4 weeks; (3) Follow-up: None.

**Period of data collection**
- Unspecified

**Notes**
- Included in review by Green, Buchbinder and Hetrick (2003).

**Methods**
- Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

**Population**
- 122 patients attending an orthopaedic and rehabilitation clinic. **Inclusion criteria:** Shoulder pain and limitation of passive shoulder ROM in all directions that interfered with ADL. Attending the orthopaedic and rehabilitation clinic. **Exclusion criteria:** Secondary adhesive capsulitis; ‘intrinsic’ causes of shoulder problems such as history of fracture or dislocation, or ‘extrinsic’ causes such as neuromuscular disorders, generalised arthritis, bilateral involvement, contraindications to NSAIDs or susceptibility to bleeding. **Mean age ± SD, % female:** Control group 58 ± 10 years, 76%; **Physiotherapy group:** 56 ± 11 years, 60%. **Setting:** Secondary or tertiary care. Study took place in Siriraj Hospital, Thailand.

**Intervention/Comparison(s)**
- **Control group** received ibuprofen 400 mg 3x daily for 3 weeks and an information sheet. This gave advice on protecting the shoulder from vigorous activities such as pushing or pulling. They were advised to use their arms normally for reaching and other ADL. They were asked to have no adjuvant therapy for the duration of the study except oral acetaminophen (up to 6g/day). They were asked to record if they received additional treatment [additional to acetaminophen?] and to keep a home exercise diary. **Physiotherapy group:** in addition to the above received a hospital-based physiotherapy programme, 3 x weekly by one of 3 research physiotherapists using standardised technique. Each session comprised: 20 minutes’ shortwave diathermy (no further details given) then mobilisation and passive stretching to tolerance. If pain occurred before end-range, exercise (see below) was considered contraindicated, but the subsequent management of any such patients is unspecified. On non-physiotherapy days members of the **physiotherapy group** were advised to apply a hot...
pack for 20 minutes, then, after 5 minutes’ interval, to do active assisted pulley exercises for 5 min, and active exercises using a towel and wall.

**Accepted outcome(s)**
SPADI. (External rotation was measured, but unclear was whether this was passive or active range.) **Adverse events: The physiotherapy group** were asked (a) whether or not they experienced pain for > 2 hours after treatment and (b) whether they had more disability next morning; **All patients** were asked by a blinded rater ‘Have the trial drugs and/or treatment programme upset you in any way?’ and examined for signs of bruises or burns during evaluation of movement. **Timing of assessments:** (1) Baseline; (2) End-point: 3 weeks; (3) Follow-up: 6, 12 and 24 weeks, though an undefined outcome – ‘successful treatment’ – was used, and any treatment was allowed after week 3.

**Period of data collection**
January–September 2001

**Notes**

**Study**
Ryan et al (2005)

**Methods**
Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: YES; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

**Population**
80 adults recruited from 20 local general practices. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder, thus: **Inclusion criteria:** > 18 years, painful shoulder in C5 distribution, > 4 weeks’ but < 6 months’ duration, limitation of active and passive ROM > 25% in both abduction and external rotation compared with the other shoulder. **Exclusion criteria:** Previous intra-articular injection or physiotherapy for this episode, evidence of glenohumeral arthritis on plain x-ray, clinical evidence of a complete cuff tear or significant cervical spine disease, history of significant trauma to the shoulder, inflammatory joint disease or a CVA affecting the shoulder, bilateral adhesive capsulitis. **Mean age ± SD, % female:** Group A 56 ± 6 years, 45%; Group B 52 ± 9 years, 68%; Group C 53 ± 8 years, 70%; Group D 55 ± 9 years, 53%. **Setting:** Primary care. Study took place in Belfast, Northern Ireland.

**Intervention/Comparison(s)**
**Injection group.** 3 ml triamcinilone was injected, half by an anterior approach (anterior glenohumeral) and half by a lateral approach (lateral subacromial), without guidance, by a single clinician. **Physiotherapy group.** 8 standardised sessions were given over 4 weeks by a single therapist or a nominated deputy. The sessions included PNF, Maitland mobilisations – which were progressed as the condition improved – standardised interferential and active exercise therapy using gym equipment. For patients receiving injection and physiotherapy, the interval between the two is unspecified. **General.** Patients who were not already taking analgesics were advised to take 1 or 2 500 mg paracetamol tablets 4–6 hourly as required, up to a maximum of 8 tablets a day. Analgesics and NSAIDs taken were recorded in a medication diary. Patients were taught a home exercise programme using a video and instruction sheet. They were asked to make a record, in their medication diary, of when they did the programme.

**Accepted outcome(s)**
22-point Shoulder Disability Questionnaire (SDQ), 100 mm VAS for daytime pain at rest, passive external rotation (to nearest 2°) using a Myrin™ OB goniometer. Adverse events in individuals were not specified as outcomes. **Timing of assessments:** (1) Baseline; (2) End-point: None; (3) Follow-up: 6, 16 and 24 weeks (but results not presented for 24 weeks).
Period of data collection
October 1998–April 2002

Notes

Study
Van der Windt et al (1998)*

Methods
Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

Population
108 patients visiting one of 60 participating GPs. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder, thus: Inclusion criteria: Painful, limited passive glenohumeral mobility, with lateral rotation relatively more restricted than abduction and medial rotation. Exclusion criteria: Indications that any condition other than ‘capsular syndrome’ was contributory to symptoms were regarded as an exclusion criterion. Other exclusions were bilateral symptoms; corticosteroid injections or physiotherapy in the preceding 6 months; contraindications to treatment; surgery, dislocation, or fractures in the shoulder region; insulin dependent diabetes; systemic disorders of the musculoskeletal system; neurological disorders. Mean age ± SD, % female: Injection group 58 ± 10 years, 47%; Physiotherapy group 60 ± 11 years, 59%. Setting: Primary care. Study took place in the Netherlands.

Intervention/Comparison(s)
Up to 3 intra-articular injections of 40 mg triamcinolone acetonide, by the posterior route, over 6 weeks versus 12, 30-minute physiotherapy sessions over 4 weeks comprising passive joint mobilisations and exercises and, optionally, ice, hot packs, or electrotherapy. Acupuncture, high-velocity thrusts and ultrasound were not permitted. Patients were allowed to continue taking drugs for pain if they had started before enrolment, and drugs could also be prescribed for severe pain.

Accepted outcome(s)
Measures included: 16-item Shoulder Disability Questionnaire (SDQ); 100-point VAS for day and night pain and improvement in passive range of external rotation. Adverse events were recorded by the clinician and by patients on their own forms. Timing of assessments: (1) Baseline; (2) In-trial and end-point: 3 weeks; (3) Follow-up: 7, 13, 26 and 52 weeks.

Period of data collection
Unspecified

Notes
Included in review by Green, Buchbinder and Hetrick (2008).

Study

Methods
Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: YES; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

Population
100 patients with stiffness-predominant frozen shoulder (‘shoulder pain is apparent mainly in the end-range of ROM’) recruited by one orthopaedic consultant from 6 hospitals. Inclusion criteria: > 50% loss of passive movement of the shoulder joint relative to the non-affected side in ≥ 1 of flexion, abduction and external rotation, duration of ≥ 3 months, ability to complete questionnaire in Dutch. Exclusion criteria: previous manipulation under anaesthetic of the affected shoulder; other conditions affecting the shoulder (e.g. rheumatoid arthritis, osteoarthritis, chondral damage, Hill-Sachs lesions, osteoporosis or malignancies); neurological deficits; pain or disorders of neck, elbow, wrist or hand; corticosteroid injection in the preceding 4 weeks. Diabetes was not an exclusion criterion. Mean age ± SD, % female: Group 1 52 ± 8 years, 65%; Group 2 52 ± 9 years, 67%. Setting: Secondary or tertiary care.
Study took place in Leiden, the Netherlands.

### Intervention/Comparison(s)
**Both groups:** Mobilisations: with both hands close to the humeral head, the therapist applied inferior, posterolateral, anteromedial and oscillatory glides, and oscillatory distraction. If range of movement increased during treatment, the techniques were performed in greater elevation and abduction. In the last 3 minutes of the treatment session, passive PNF patterns were performed in the pain-free range, followed by pendular exercises in prone. Concurrent interventions apart from self- or physician-prescribed pain medications were disallowed in the first 3 months of the study. **Group 1:** High grade mobilisations (Maitland’s grade III-IV) with standard precautions. The duration of time on stretch depended on the individual patients’ responses. **Group 2:** Low grade mobilisations (Maitland’s grade I-II), again, with standard precautions. **Both groups:** Treatments were twice weekly for 12 weeks. Thereupon further management was decided by the orthopaedic consultant and patient. For continued physiotherapy, if required, patients were referred to private practice.

### Accepted outcome(s)
Shoulder rating score; pain during movement, at rest, and at night using a VAS; passive external rotation measured using a goniometer. **Adverse events:** Participants’ opinions on their shoulder function relative to baseline were sought, but ‘much worse’, ‘worse’ and ‘no change’ categories were combined in the Results. Follow up was at 3, 6 and 12 months. **Timing of assessments:** (1) Baseline; (2) End-point: 3 months; (3) Follow-up: 6 and 12 months.

### Period of data collection
August 1999–March 2002

### Notes
The therapists administering the high grade mobilisation were trained, whereas those administering the low grade mobilisations were not. There was no non-intervention group, so it is unclear whether either intervention is better than doing nothing.

### Study
Yang et al (2007)

### Methods
Eligibility criteria specified: YES; Random allocation: YES; Concealed allocation: YES; Groups similar at baseline: YES; Blinding of subjects: NO; Blinding of therapists: NO; Blinding of assessors: YES; Intention-to-treat: YES; point measures and measures of variability: YES.

### Population
28 patients with painful, stiff shoulder recruited from a Department of Physical Medicine and Rehabilitation. Probably a mix of pain-predominant and stiffness-predominant frozen shoulder, thus: **Inclusion criteria:** Painful, stiff shoulder for ≥ 3 months, limited range of movement (≥ 25% versus the contralateral shoulder in at least 2 of flexion, abduction or medial and lateral rotation) and consent of patient and physician. **Exclusion criteria:** Diabetes, history of surgery on affected shoulder, rheumatoid arthritis, history of severe trauma, fracture in the shoulder region, rotator cuff rupture, tendon calcification. **Mean age ± SD, % female:** Group A-B-A-C 53 ± 7 years, 93%; Group A-C-A-B 58 ± 10 years, 79%. **Setting:** Secondary or tertiary care. Study was conducted at the National Taiwan University Hospital.

### Intervention/Comparison(s)
**A:** 10-15 repetitions of mid-range mobilisation as described by Maitland and Kaltenborn, with the supine patient’s shoulder abducted 40°. **B:** End-range mobilisation as described by Vermeulen et al. and Maitland; 10-15 repetitions of ‘intensive mobilising techniques’ were applied with the humerus at end-range in different directions. **C:** Mobilisations with movement (MWMs) as described by Mulligan. A belt was placed round the seated patient’s proximal humerus to glide the humeral head appropriately. One of the therapist’s hands was used over the appropriate aspect of the head of humerus, while the other applied counter pressure to the scapula. ‘The glide was sustained during slow active shoulder movements to the end of the pain-free range and released after return to the starting position.’ The technique was repeated in 3 sets of 10, with 1 minute rest between sets. **All groups:** No
instruction in home exercises was given, and the patients were frequently asked not to do exercises. The Sequence of interventions was A-B-A-C and A-C-A-B with each component being 3 weeks: hence a total of 12 weeks.

Accepted outcome(s)  A self-administered scale, the Flexi-level scale of Shoulder Function (FLEX-SF). Adverse events in individuals were not specified as an outcome. *Timing of assessments:* (1) Baseline; (2) In-trial and end-point: 3, 6, 9 and 12 weeks; (3) Follow-up: None.

Period of data collection  Unspecified

Notes  Trials marked ‘*’ were included in the review by Green, Buchbinder and Hetrick (2003)

Asterisked studies were included in the Cochrane review by Green, Buchbinder and Hetrick (2003)
APPENDIX D: References to excluded studies

This reference list is limited to articles identified in the supplementary search but excluded from analysis (see APPENDIX A: Methods, and APPENDIX C: Table of excluded studies).

Whitman JM, Fritz JM, Boyles RE (2003). Is there evidence that performing joint manipulation under local anesthetic block might be more effective than continuing a program of joint mobilization, stretching, and mobility exercises in a woman with recalcitrant adhesive capsulitis of the shoulder? *Physical Therapy*, 83, 5, 486-496.
i. Physiotherapy versus other physiotherapy

**Author(s):** Carette et al 2003, Ryans et al 2005  
**Question i.i.** Should we add outpatient physiotherapy to home exercises for both stages of contracted (frozen) shoulder?  
**Settings:** Primary care in Canada, secondary care in Northern Ireland.

\(^1\) The 95% CI crossed zero. The MCID is not known, but any potential effect would be of questionable clinical significance.

\(^2\) Validated, patient self-reported functional outcome measures.

\(^3\) The effects were in different directions, but there was considerable overlap of the 95% CIs.

\(^4\) The 95% CI crossed zero and the threshold for the MCID favouring addition of outpatient physiotherapy.

\(^5\) Validated, patient self-reported pain scores.

\(^6\) Likely, although threshold for MCID not known.
Validated, patient self-reported pain score, but threshold for MCID not known.

The 95% CI did not cross zero. The MCID is not known, but any potential effect would be of questionable clinical significance.

Probably of limited importance from the patients' perspective.

**Author(s): Ginn and Cohen (2005)**

**Question i.ii.** Should we use a home muscle function retraining programme or outpatient physiotherapy (with passive mobilisations) and standard home exercises for contracted (frozen) shoulder?

**Settings:** Secondary care in Australia.

2. The 95% CI crossed zero and the threshold for MCID on the side favouring steroid injection.
3. The 95% CI crossed zero and the threshold for MCID on either side.
4. Validated, patient self-reported pain outcome.
5. Mixed-stage, but it is unclear whether physiotherapy interventions were modified according to stage, reflecting typical clinical practice.
6. The 95% CI did not cross zero. The MCID is not known but any potential change would be of questionable clinical importance.
7. Probably of limited importance from patients' perspectives.

iv. Adding physiotherapy to other treatments

Author(s): Buchbinder et al (2007)

**Question iv.i.** Should we add outpatient physiotherapy (with passive mobilisations) and home exercises to distension for both stages of contracted (frozen) shoulder?

**Settings:** Primary and secondary care in Australia.

8. $P = 0.002$

9. Probably of limited importance from the patients' perspective.

10. The 95% CI crossed zero. The MCID is not known for this outcome, but any effect within the 95% CI would be of questionable clinical significance.

**Author(s):** Kivimäki et al (2007)

**Question vi.ii.** Should we add MUA to home exercises for both stages of contracted (frozen) shoulder?

**Settings:** Secondary care in Finland.

Data not reported in usable format.
APPENDIX F: Delphi panellists

Our invited Delphi panel included patients and targeted physiotherapists (shoulder experts and musculoskeletal generalists from primary and secondary care settings), managers and specialist shoulder surgeons. With a view to optimising the guidelines’ usefulness across the range of intended users, the aim was to reach agreement—at an early stage in the guidelines’ development—on factors such as layout, and depth and style of reporting. It was expressly not our intention that achieving a consensus on ‘best practice’ would fall within panel’s remit, nor that the panel would evaluate the final product\(^9\). Instead, its role was formative.

Specifically, we chose our Delphi expert panel to represent the following groups:

- patients receiving physiotherapy for frozen (contracted) shoulder;
- other members of the public;
- targeted shoulder specialist physiotherapists;
- a sample of musculoskeletal generalist physiotherapists; and
- targeted managers and specialist shoulder surgeons.

The individual Delphi panellists were:

- Mrs Christine Baldwin (service user/member of the public)
- Mr David Burton, Consultant Orthopaedic Surgeon, Darlington Memorial Hospital, Darlington
- Professor Andrew Carr, Nuffield Professor of Orthopaedic Surgery, Nuffield Orthopaedic Hospital, Oxford
- Mr Drew Coverdale, private physiotherapy practitioner and Lecturer, MACP
- Dr John Fordham, Consultant Rheumatologist, James Cook University Hospital, Middlesbrough
- Mr Gary Goodchild (service user/member of the public)
- Mrs Anne Hardy, Extended Scope Practitioner in Physiotherapy, Middlesbrough and Redcar & Cleveland Community Services
- Mrs Denise Jones, Lecturer in Physiotherapy, Teesside University, and private practitioner
- Dr Jeremy Lewis, Consultant Physiotherapist, St. Georges Hospital London and Research Lead, Therapy Department, Chelsea and Westminster Hospital, London
- Ms Jane Moser, Specialist Physiotherapist, Nuffield Orthopaedic Hospital, Oxford
- Mrs Janice Murphy (service user/member of the public)
- Professor Amar Rangan, Consultant Orthopaedic Surgeon, James Cook University Hospital, Middlesbrough and visiting professor, Teesside University
- Dr Jim Robertson, General Practitioner with Special Interest in Musculoskeletal, Middlesbrough and Redcar & Cleveland Community Services
- Mr Paul Thurland, Assistant Director, Specialist Services, Middlesbrough and Redcar & Cleveland Community Services.

\(^9\) This role fell to the CSP’s Good Practice Panel (methods) and external reviewers (specialist subject content)

APPENDIX H: Deviations from protocol

We deviated from our pre-defined protocol in four instances, as set out below.

Our aims originally included, ‘to standardise physiotherapists’ diagnosis, assessment and management of contracted (frozen) shoulder’ and to ‘standardise a care pathway for patients/service users utilising best practice in the diagnosis, assessment and physiotherapy management of contracted (frozen) shoulder’. We abandoned both because we felt they were excessively prescriptive.

Our objectives included ‘to identify and systematically appraise the best available evidence relating to the physiotherapy management of contracted (frozen) shoulder’. We modified this to ‘to systematically review the best available evidence relating to the physiotherapy management of contracted (frozen) shoulder’. This more precisely reflected our intended and actual conduct of the review.

Finally, we did not anticipate that our systematic review of physiotherapy management for contracted (frozen) shoulder we would identify so many comparisons, nor that so many would be in trials with a moderate-to-high risk of bias. Our response to this contingency was to restrict further analysis to trials which we judged, by transparent processes, to have a low risk of bias. We took this course with the users of the guidelines in mind, in the interests of conciseness and clarity.
APPENDIX I: Guidelines Development Group profiles

Co-leads

Nigel Hanchard PhD, MSc, MCSP, HPC, FCO (Fellow of the Cyriax Organisation), PGD (tertiary level teaching), PGD (injection therapy) is an experienced clinician and teacher at pre- and post-registration levels, and formerly led the pre-registration MSc in Physiotherapy at Teesside University. He is a faculty member of the M-level module, ‘diagnosis and treatment of shoulder conditions’ at Teesside University. He has conducted research into the diagnosis and treatment of shoulder pain, and is a recipient of the CSP’s Robert Williams award for work in this area. His publications include first authorship of the CSP shoulder impingement guidelines and review and primary research articles. He is a member of the international Cochrane workgroup developing systematic diagnostic reviews, a Cochrane author and an editor of the Cochrane Bone, Joint and Muscle Injuries Group; and a co-applicant on and member of the Advisory Group for a major HTA-funded investigation into contracted (frozen) shoulder. His other memberships include the British Elbow and Shoulder Society and the CSP’s Dynamic Ultrasound Group.

Lorna Goodchild MSc, MCSP, HPC, MMACP, PGC (Sports Injury Management), PGD (injection therapy) is an Extended Scope Physiotherapist based at James Cook University Hospital, Middlesbrough. She has six years’ experience as an upper limb specialist working in collaboration with a consultant shoulder surgeon. Responsibilities of her post include conducting new patient assessment clinics where patients presenting with complex shoulder problems are triaged. She orders investigations and lists patients for surgical procedures. She also conducts clinics for preoperative assessment and postoperative review. She is a faculty member of the M-level module, ‘diagnosis and treatment of shoulder conditions’, a guest lecturer of the M-level ‘sports injury management’ module and examiner for the MSc ‘Management of patients with neuromusculoskeletal dysfunction’ at Teesside University. She is a published researcher, and her co-authorships include a Cochrane review. She is a member of the Trial steering committee for the HTA funded ProFHER Trial (Proximal Fractures of the Humerus Evaluation by Randomisation); as well as a co-applicant on and member of the Advisory Group for a major HTA-funded investigation into contracted (frozen) shoulder. Her society memberships include the British Elbow and Shoulder Society.

Members

Dot Davison BSc, MCSP, HPC is a community-based clinical specialist physiotherapist in general musculoskeletal management, with experience in guidelines development.

Sibongile Mtopo MSc, BSc (Hons), MCSP, HPC, MBAHT is a specialist physiotherapist (upper limb and hand). Her current role involves dealing with complex hand and shoulder disorders. She has a keen interest in research and evidence-based practice.
Tracey O'Brien MCSP, HPC, PGD (Manipulative Therapy), MSOM, PGD (Injection Therapy) is an experienced clinician in musculoskeletal medicine who has a special interest in shoulders. She has six years experience working as an extended scope practitioner for Middlesbrough, Redcar and Cleveland Community Services as part of the Musculoskeletal Service. Her role includes triaging orthopaedic referrals and providing upper and lower limb clinical assessment clinics in the community. This includes ordering investigations and direct referral into the orthopaedic and rheumatology directorates. She has been involved as an investigator and facilitator in several clinical trials.

Christine Richardson MCSP, HPC, PG Dip (injection therapy) is a community-based clinical specialist physiotherapist in musculoskeletal, with a special interest in shoulder disorders.

Martin Scott MSc, BSc, MCSP, HPC is a clinical specialist physiotherapist (shoulders). He is a founder member of the International Board of Shoulder & Elbow Therapists and a winner of the British Elbow & Shoulder Society AHP Fellowship (2005). He has presented scientific papers and posters of original research at national and international conferences of shoulder surgery & physiotherapy since 2001, and lectures internationally on the shoulder and physiotherapy.

Jackie Thompson MCSP, HPC, PG (mobilisation/manipulative therapy), PGD (injection therapy). Jackie Thompson is an Extended Scope Physiotherapist with a special interest in the shoulder. She works alongside the upper limb consultant surgeons in joint clinics and triages the referrals into the orthopaedic directorate.

Mary Wragg MCSP, HPC, MSOM, MMACP (assoc), PGD (injection therapy) is an ESP shoulder specialist who works in collaboration with a consultant shoulder surgeon. She independently conducts clinics where she diagnoses and triages shoulder conditions, ordering special investigations at her discretion, and is authorised to list patients for surgical procedures such as decompression, stabilization and arthroplasty. She also reviews patients post-operatively at her ESP-led shoulder clinic.

Helen Watson BSc, MCSP, HPC, PG (injection therapy) has been a clinical specialist and Extended Scope Physiotherapist in shoulders at the Freeman Royal Hospital since 2001. Her research experience includes running clinical trials and interpreting clinical data. She has co-authored primary research articles in peer-reviewed journals and presented research papers nationally and internationally.
